DNA VIRUSES

SUBSECTION 3 *ADENOVIRIDAE*

CHAPTER 155

Adenoviruses

James D. Cherry • Santhosh Nadipuram

Adenoviruses, which are responsible for a varied array of illnesses in children,* are associated most commonly with respiratory illness and gastroenteritis, but cardiac, neurologic, cutaneous, urinary, and lymphatic manifestations also occur frequently. Although many of the clinical manifestations of adenoviral infections are distinctive, the specific viral etiologic agent rarely is recognized by physicians.

Adenoviruses were noted first in explant cultures of human adenoid tissue; this finding, plus the observation of their apparent general affinity for lymphatic tissue, led to the designation of their name.[165,174,199,526]

HISTORY

The first adenoviral strains were not isolated until 1953, when tissue culture techniques became available, although epidemic disease caused by adenoviruses had been observed throughout the first half of the 20th century. Epidemic keratoconjunctivitis first was noted and reported in Austria by several physicians in 1889.[4,205,508,538,564] Major outbreaks of epidemic keratoconjunctivitis were reported in Bombay in 1901, in Madras in 1920 and 1928, in Hawaii in 1941, and on the West Coast of the United States in 1942.[267,288,289,345,653]

Epidemics of illness such as pharyngoconjunctival fever were observed throughout the 20th century. Béal,[33] in 1907, was the first to report the syndrome; in the 1920s, epidemics associated with swimming in public pools and in lakes were noted in Germany and the United States.[26,473] Initial studies by Rowe and colleagues[526] revealed cytopathic changes in explant tissue cultures of human adenoids that had been removed surgically. Fluid from these cultures caused distinctive cytopathologic changes in other tissue cultures, and antiserum prepared in hyperimmunized rabbits neutralized the effect. In 1954, Hilleman and Werner[282] isolated similar cytopathic agents from the throat washings of military recruits with febrile acute respiratory disease. Shortly thereafter, epidemic keratoconjunctivitis and pharyngoconjunctival fever were seen to be illnesses of adenoviral etiology.[127,130,132,309]

Initially, adenoviruses were known by the following names: *adenoid degeneration agent* because of its recovery in human adenoid tissue explants[526]; *respiratory illness patient number 67 (RI-67) agent*, which was recovered from a military recruit with primary atypical pneumonia during an epidemic of acute respiratory disease[281,282]; *adenoidal-pharyngeal-conjunctival agent*[297]; and *acute respiratory disease agent.*[110] In 1956, investigators in the field selected the term *adenovirus* for the new group of viruses. The name suggested the characteristic involvement of lymphadenoid tissue, as well as the tissue from which the organism was first isolated.[165]

Because of considerable morbidity and major economic considerations related to adenoviral epidemic respiratory disease in military recruits, the development of vaccines received attention early. Initially, inactivated vaccines were produced and they achieved some degree of success.[245,280,371] Later, live viral preparations grown in diploid human fibroblast tissue culture became available and proved quite successful in controlling specific adenoviral infections in military service personnel.*

In 1975, enteric adenoviruses (adenovirus types 40 and 41) first were reported.[432,540,639] They were demonstrated by electron microscopy and subsequently were shown to be a significant cause of diarrhea in children.† Especially important today are adenoviral infections in immunocompromised hosts, particularly transplant recipients.[350]

PROPERTIES OF THE VIRUS

Classification

Adenoviruses that infect humans are placed in the family *Adenoviridae* and the genus *Mastadenovirus.*[183,290,416,543] At present, 57 immunologically distinct adenoviral

*References 2, 3, 63, 65, 97, 163, 199, 285, 292, 357, 516, 530, 557, 610.

*References 153, 154, 234, 371, 521, 556, 585, 588.
†References 63, 104, 356, 424, 474, 584, 598, 610.

types have been recovered from humans.* Additional adenoviral types have been isolated from monkeys, cattle, dogs, mice, and chickens.[270,272,274] Mammalian adenoviruses have a common generic antigen that can be identified by complement fixation and enzyme-linked immunosorbent assay (ELISA).[315,486,518,641] Individual serotypes are identified by neutralization.[251,256,342]

Adenoviruses originally were subclassified on the basis of four hemagglutination patterns with rat and rhesus monkey red blood cells.[522] This subclassification is updated in Table 155-1. In 1962, researchers found that adenovirus type 12 could cause tumors in hamsters, and soon thereafter investigators realized that adenoviruses also could be classified by their oncogenic potential in rodents.[295,591] Grouping by oncogenic potential was similar, with few exceptions, to grouping by hemagglutination properties: organisms in hemagglutination group I had moderate oncogenic potential, group II and group III organisms had low or no potential, and group IV organisms had high oncogenic potential.[225,291,303]

Adenoviruses also have been subclassified (A to F) on the basis of the percentage of guanine plus cytosine in their DNA and other biochemical and biophysical criteria* (Table 155-2). In general, subgroup A organisms are the same as hemagglutination group IV; subgroup B, the same as hemagglutination group I; subgroups C, E, and F, the same as hemagglutination group III; and subgroup D, the same as hemagglutination group II. Restriction enzyme analysis has resulted in genomic typing of specific adenoviral serologic types.[380] In particular, numerous genotypes of adenovirus type 7 have been identified and the severity of disease may relate to the genotype.

TABLE 155-1 **Separation of Human Adenoviruses into Subgroups by Ability to Agglutinate Rhesus Monkey and Rat Erythrocytes**

Subgroup	Characteristic	Type
I	Complete agglutination of monkey erythrocytes	3, 7, 11, 14, 16, 21, 34, 35, 50
II	Complete agglutination of rat erythrocytes	8-10, 13, 15, 17, 19, 20, 22-30, 32, 33, 36-39, 42-49, 51
III	Partial agglutination of rat erythrocytes	1, 2, 4-6, 40, 41
IV	No or little agglutination of monkey or rat erythrocytes	12, 18, 31

Data from references 135, 270, 276, 284, 287, 327, 340, 371, 457, 458, 539, 643.

Physical Properties

Adenoviruses are nonenveloped DNA viruses 65 to 80 nm in diameter.† The virion consists of a protein capsid composed of 252 capsomeres and a nucleoprotein core that contains the DNA viral genome and two to four internal proteins.[500] The virion is roughly spherical in the form of an icosahedron; each of the 20 sides is an equilateral triangle, with the vertices of each converging in groups of five and resulting in 12 pentagonal vertices.[63,199,290] Each vertex capsomere contacts five other capsomeres and is designated a *penton*. Each penton contains a base plate and a rodlike projection, the fiber. The virion has 240 nonvertex capsomeres that occur in groups of six and are known as *hexons*.[349,458,600] Hexons contain the generic complement-fixing antigen.[199] Each capsomere has a diameter of 8 nm and a central hole that is 2 to 3 nm in diameter.[648] The capsomeres constitute 87 percent of the dry weight of the virion.

The central core of the virion, which accounts for 12 to 14 percent of its dry weight, is composed of linear

TABLE 155-2 **Grouping of Human Adenoviral Serotypes Based on Biochemical and Biophysical Criteria**

Subgroup	Adenovirus Type(s)	Location and Manifestations of Infection
A	12, 18, 31	Gastrointestinal; may cause disease in children
B:1	3, 7, 16, 21, 50, 55	Respiratory, eye, and gastrointestinal symptomatic infections
B:2	11, 14, 34, 35	Urinary and respiratory; symptomatic urinary tract infections (particularly in immunosuppressed patients) and symptomatic respiratory infections
C	1, 2, 5, 6, 57	Respiratory and gastrointestinal; symptomatic respiratory infections and hepatitis in immunosuppressed patients
D	8-10, 13, 15, 17, 19, 20, 22-30, 32, 33, 36-39, 42-49, 51, 53, 54, 56	Eye and gastrointestinal; symptomatic eye infections, gastrointestinal infections in HIV-infected patients
E	4	Symptomatic eye and respiratory infections
F	40, 41	Symptomatic gastrointestinal infections
G	52	Symptomatic gastrointestinal infections

double-stranded DNA (molecular mass, 23.85 × 10^6 daltons for adenovirus type 2) and two to four basic proteins.[207,291,648]

Adenoviruses are highly stable in general.[142,199,223,303,373] They are resistant to lipid solvents and retain activity at pH values ranging from 2 to 10.

At 24° C, maximal infectivity is maintained between pH 6.0 and 9.5. Adenoviruses are stable at room temperature for 2 weeks, at 36° C for 7 days, and at 4° C for at least 70 days. Infectivity is destroyed by heating to 56° C for 30 minutes. Sodium dodecyl sulfate (0.25%) inactivates virus by disruption of the capsid.[349] Hydrogen peroxide vapor has been shown to inactivate adenoviruses,[47] and free chlorine is effective in controlling adenoviruses in drinking water.[475] Adenovirus serotypes 2, 10, 40, and 41 are highly resistant to ultraviolet radiation, and, therefore, they can be used as markers of the quality of water treatment practices.[279]

Antigenic Composition

The antigenic determinants of adenoviruses are contained on the protein structural subunits (hexons, pentons, and fibers).[600] The hexon antigen (alpha component) carries the generic antigenic component that is common to all mammalian adenoviruses and is measured by complement fixation or ELISA. Another hexon antigen (epsilon component) reacts with neutralizing antibodies lacking hemagglutination-inhibiting activity. The antigen related to viral fiber also induces the production of type-specific neutralizing antibody for some adenoviral types. Minor antigens are related to the pentons. One of them (the cell-detaching factor) causes rounding and clumping of tissue culture cells.

Gerna and associates,[221] using the immunoperoxidase antibody technique, found that the early antigens of all serotypes belonging to one group (see Table 155-1) react strongly with all type-specific immune sera of the same group.

Tissue Culture Growth

Although adenoviruses can be grown in a wide variety of cells of human epithelial origin, primary or diploid cultures of human embryonic kidney are preferable for recovery of agents from clinical specimens.[373] Continuous cell lines such as HeLa and HEp-2 also are quite sensitive.[266,303,514,527] Adenoviruses will grow in monkey kidney tissue culture, but evolution of the cytopathic effect is considerably slower than that occurring in cells of human origin. In addition, the cytopathic effect is more variable in monkey kidney tissue culture and many isolates will be missed.

Enteric adenoviruses have been detected in human feces by electron microscopy.* These enteric adenoviruses, identified as types 40 and 41, usually do not grow in standard tissue culture systems. Both viral types will grow in Graham 293 cells (a human embryonic kidney cell line transformed by adenovirus type 5); type 40 also will grow in tertiary monkey kidney cells, and some strains of type 41 will grow in HEp-2, Chang conjunctiva cells, and tertiary cynomolgus cells.[576,625] Grabow and associates[237] noted that the PLC/PRG/5 cell line was 100 times more sensitive to a laboratory strain of adenovirus type 41 and 10 times more sensitive to a laboratory strain of adenovirus type 40 than were Graham 293 cells.

Specimens for viral culture may be obtained from the eye, pharynx, blood, lungs, pleural and pericardial fluid, liver, stool, intestinal epithelium, lymph nodes, cerebrospinal fluid (CSF), brain, urine, and renal tissue. For best isolation rates, clinical specimens should be inoculated in cell culture within 6 hours of being collected. Tissue culture tubes are incubated best at 37° C, and rolling offers no advantage over stationary incubation.[373] Although the cytopathic effect has considerable variability, the most consistent finding is marked rounding and clumping of cells, often in grapelike clusters.[500,504] A cytopathic effect may be noted as early as 1 to 2 days after inoculation, but it may be delayed as long as 4 weeks. Use of the shell viral technique, in which infected cells in a specimen are centrifuged onto HEp-2 tissue culture cells, yields positive cultures in 1 to 2 days.[171] The cytopathic effect characteristically is followed by detachment of the entire cell sheet from the glass of the tissue culture tube within 2 to 4 days.[242,267,487,524,527]

Virus Multiplication

Initial attachment of adenoviruses to cells is relatively slow, with up to 6 hours being required.[128,224,303] The fiber protein of the virus mediates attachment to the cellular receptor.[544] An important adenovirus receptor is the coxsackievirus and adenovirus receptor (CAR) protein. It is a high-affinity receptor for all adenoviral subgroups except subgroup B. Penetration into the host cell occurs rapidly, either by phagocytosis or by direct entry through the plasma membrane.[303,391] The eclipse period with adenoviruses varies from 11 to 21 hours, depending on the serotype.[224,303] During eclipse, viral DNA uncoating requires approximately 2 hours when determined biochemically.[303] After uncoating, the viral DNA rapidly enters the nucleus of the cell and disassociates from its internal protein.[128,225,391] After the eclipse period, viral DNA accumulates, often doubling the content of the infected cell and becoming part of the typical inclusion bodies of the infected cells.[225]

Characteristic cytopathic changes in tissue culture, as demonstrated by light microscopy of hematoxylin and eosin–stained material or by electron microscopy, appear as early as 8 to 24 hours after infection occurs.[59,61,251] Two types of intranuclear alterations may be seen. In the first, early, small, discrete eosinophilic inclusions are observed. They gradually enlarge, become more prominent, and then form a large crystalline central mass surrounded by a clear zone or halo.[59,231] This type of early cytopathic effect appears to take place in cells that contain only small amounts of infectious virus.[60] The second type of intranuclear alteration, which generally occurs later, consists of large basophilic intranuclear inclusions.[59] Occasionally, giant forms measuring greater than 14 mm across are noted.[59] These mature inclusions may expand the nucleus of the cell so greatly that the cell's DNA content

*References 63, 120, 136, 315, 340, 507, 517, 597, 623, 641.

is 10 times larger than that of an uninfected cell. They contain a large amount of viral antigen and infective virus. Cytopathic changes vary considerably with the different adenoviral serotypes.[61,349]

In general, virus remains within the nucleus of intact, infected cells, with less than 1 percent of the total viral content of a culture being free within the extracellular fluid at any one time.[349]

Animal Susceptibility

Human adenoviruses usually do not produce clinical illness in laboratory animals, although infections with several different serotypes have occurred in selected animals.[303] When adenoviral strains were administered intranasally to young, "pathogen-free," colostrum-deprived pigs or 1-month-old cotton rats, pneumonia developed in the animals and intranuclear inclusions were observed microscopically in their lungs.[303,472] An adenovirus type 5 strain was injected intravenously into a rabbit, and the virus was recovered from the animal's spleen when removed 2 months later. Many adenoviral strains will propagate in a variety of different animal tissue cultures. In addition, in some cultures, marked cytopathic effects are observed but little infectious virus is produced.

Adeno-associated Viruses

Adeno-associated viruses are a group of small, defective, single-stranded, DNA-containing, virus-like particles that replicate in tissue culture only in the presence of adenoviruses.* Four serologic types have been identified; however, only types 2 and 3 have been recovered from humans.[199,349] These agents have been isolated from throat and anal swab specimens of children from whom adenoviral strains also were isolated.[53] Approximately 30 percent of children have complement-fixing antibody to adeno-associated virus types 2 and 3; most of these children have had evidence of adenoviral infection as well.[54] Neutralizing antibody to adeno-associated virus types 2 and 3 is noted in the sera of 60 to 80 percent of children 8 to 14 years of age.[481] The specific relevance of adeno-associated viruses is unknown.

EPIDEMIOLOGY

General Prevalence

Adenoviral infections account for 2 to 5 percent of all respiratory illnesses.† In children, adenoviruses are estimated to be responsible for 2 to 35 percent of respiratory viral illnesses,‡ and they are implicated in 5 to 11 percent of upper respiratory tract infections, 4 to 10 percent of cases of pharyngitis, 3 to 9 percent of cases of croup, 5 to 11 percent of cases of bronchitis, 2 to 16 percent of cases of bronchiolitis, and 4 to 10 percent of cases of pneumonia.* Enteric adenoviral infections are the cause of 2 to 15 percent of acute diarrheal illnesses in children.†

Specific categories of illness caused by adenoviruses vary with respect to viral serotype, patient age, socioeconomic status, and environmental conditions.‡ Adenoviruses have a predilection for infants and children younger than 5 years of age who spend portions of their days in closed environments, such as daycare centers, orphanages, and other institutions.§ Epidemics of disease caused by adenoviral infection have been associated with swimming pools, daycare centers, resident schools, certain industries, hospitals, physicians' offices, and early basic military training centers in young recruits.¶ Adenoviruses are recovered commonly from children in tropical countries and in situations characterized by crowding, such as lower socioeconomic settings.[85,90,107,316,662]

Age Incidence and Prevalence

Although adenoviral infections occur in all age groups, the incidence of infection generally is related inversely to age.[114,349] More than 90 percent of neonates have transplacentally acquired complement-fixing adenoviral serum antibody.[449,565] Most infants have neutralizing antibody to one or more of the common adenoviral types, which appears to be protective during the first 6 months of life. When adenoviral infection does occur in a neonate, it often is severe and occasionally fatal.[16,177,670] By the sixth month of life, only 14 percent of infants have demonstrable adenoviral complement-fixing antibody. By the time children reach 1 year of age, complement-fixing adenoviral antibody is observed in 44 to 50 percent of sera tested.[297,453]

The incidence of adenoviral infection peaks in infants and children between 6 months and 5 years of age.[102,422,488] By the time that they are 5 years of age, 70 to 80 percent of children have neutralizing antibody to adenovirus types 1 and 2 and 50 percent have antibody to adenovirus type 5.**

Adenoviral infections also occur commonly in grade school– and junior high school–aged children, but the incidence diminishes in high school–aged adolescents. Adenoviral infections occur in only 1 to 2 percent of college students, and they are noted infrequently in civilian adults.[172,173,175,241,567] Approximately 1 percent of adults with a respiratory infectious illness will have adenoviral infection; in hospitalized adults, the incidence is approximately 4 percent.[241] The most common adenoviral respiratory tract infections in children are caused by types 1, 2, 3, and 5.†† Types 6 and 7 are the next most frequent isolates associated with childhood respiratory tract infection. Adenovirus types 40 and 41 are the most common causes of diarrhea.[104,354,377]

Military Recruits

Epidemic adenoviral disease occurs commonly in military recruits, with virtually all illness developing during the first 8 weeks of basic training.* The attack rate has varied between 40 and 90 percent.[195,242,398,604] Adenoviruses account for 30 to 70 percent of acute respiratory disease, 67 percent of common cold-like illnesses, 62 to 77 percent of cases of acute febrile pharyngitis and tonsillitis, 67 percent of cases of bronchitis, and 24 percent of cases of pneumonia.[46,196] Some adenoviral infections are associated with minimal or no symptoms.[196,242]

A vaccine against adenovirus serotypes 4 and 7 was developed for use in military basic training centers and effectively prevented outbreaks of adenovirus. Routine vaccination began in 1971, but the sole manufacturer of the vaccine ceased its production in 1995. The first large post–vaccine era outbreak of adenovirus serotypes 3 and 7 occurred in naval recruits in Great Lakes, Illinois, in 1997.[531] Subsequent adenoviral epidemics occurred in military recruits in Fort Jackson, South Carolina, in 1998 with type 4 and in Lackland Air Force Base in San Antonio, Texas in 2007 with serotype 14.[68,580,620]

The last remaining stocks of vaccine were depleted or expired by 1999. Because of continued outbreaks, vaccine development was reinitiated, leading to the development of a live oral vaccine against adenovirus 4 and 7. The vaccine was licensed in 2011. It is currently manufactured by Barr Labs.[598] A full review of 8 deaths caused by adenovirus infection in military recruits from 1999 through 2010 was published by Potter and colleagues. All 8 deaths occurred after the cessation of the immunization program in 1999. In contrast, there were no deaths due to adenovirus infection in U.S. military personnel from 1975 through 1998 while this program was in place.[499]

Geographic Distribution

Adenoviral infections have been noted throughout the world.† Epidemic, endemic, and sporadic infections all occur.

Seasonal Patterns

Sporadic infections with adenoviruses occur throughout the year.‡ Epidemic adenoviral respiratory disease usually occurs in the winter, spring, and early summer.§ Seasonal patterns depend on serotypes, population groups, and exposure. Epidemics of disease in military recruits commonly associated with adenovirus types 4 and 7 occur most frequently in the winter and spring.[55,195,196,280] Epidemics of pharyngoconjunctival fever have been noted most commonly in the summer months in school-aged children in association with summer camps or swimming pools.[404,607,648] No seasonal pattern has been identified for adenoviral gastroenteritis.[120,339,517,597]

Host and Social Factors

The overall incidence of adenoviral illnesses is higher in males.[114,267] In a study involving 3313 adenovirus isolates, the male-to-female ratio was 1.3 : 1.[114]

Susceptibility to adenoviral infection apparently does not vary by race. More severe disease has been noted in infants of native and Indian populations in New Zealand and Canada.[9,36,232] However, the relationship of these findings to socioeconomic conditions was not identified initially.

The incidence of adenoviral infection is greatest in lower socioeconomic population groups.[316] Spread of infection has been observed in daycare centers, schools, children's homes, hospitals, clinics, physicians' offices, and certain industrial settings.* Acute, overwhelming illness, including bronchiolitis and pneumonia with severe pulmonary residua, has been reported in neonates, small infants, and occasionally, adults.[16,265,376] Adenoviral infections are a significant problem in immunocompromised hosts; when they occur, they frequently are severe and occasionally are fatal.†

Spread of Infection

Adenoviruses frequently are isolated from the conjunctiva, throat, and stool. Despite the ease of isolating the virus, the effectiveness of spread of infection in the general population varies considerably.[90] Adenovirus types 1, 2, 3, 5, and 7 are effective spreaders; however, they are not as highly contagious as varicella, measles, and influenza viruses.[89,90] Close contact appears to be necessary for infection to spread from one person to another.[565] Illness does not spread rapidly in the usual school setting but does spread dramatically in closed environments.[43,89,257,296] Although adenovirus type 4 spreads less effectively in the general population, spread is rapid in nonimmune military recruits who live in close contact with each other.[100] In an outbreak of adenovirus type 7 in a children's home, 84 percent of the residents were shown to be infected.

Transmission of virus occurs by droplets reaching the conjunctiva, nose, or throat or, alternatively, by the fecal-oral route. In volunteer studies, adenoviruses have been shown to spread by small-droplet aerosols and, to a lesser degree, by large droplets.[19,115,116] Adenovirus type 4 has been recovered from room air and cough samples of patients with the virus in their throats.[20] A study by Russell and colleagues[529] of 341 military recruits and support personnel at the Marine Corps training center in San Diego, California, demonstrated that more than 79 percent of incoming recruits were susceptible to adenoviral infection in the postvaccine era. They identified incoming recruits with prolonged asymptomatic shedding of adenovirus and

the presence of adenoviruses on multiple living quarter surfaces as potential sources of transmission. They also found evidence of extended pharyngeal shedding of adenovirus over the course of several days among recruits who had febrile respiratory illnesses.

In epidemics of pharyngoconjunctival fever, the virus appears to spread from contaminated swimming pool water to the eyes of recipients. In non–swimming-associated outbreaks of adenoviral respiratory illness with appropriate serotypes, conjunctivitis occurs only rarely.* This fact, in conjunction with the finding that pharyngoconjunctival fever occurred after conjunctival administration of virus, but not after nasopharyngeal application in volunteers,[39,557,634] suggests that the conjunctiva must be inoculated directly for the syndrome to occur. Epidemics of keratoconjunctivitis have occurred as a result of contact with contaminated ophthalmic instruments and fingers.† In daycare centers, orphanages, and the military, transmission probably occurs most commonly through small-droplet aerosols in crowded quarters.[495] An alternative in children is the fecal-oral route. Enteric adenoviruses have been identified in fecal specimens for approximately 8 days after the onset of gastroenteritis.[339]

Family members may excrete adenoviruses in their feces intermittently for prolonged periods after initial infection.[65,197] In one study, 20 percent of persons excreted adenoviruses in stool for longer than 3 months. Intrahousehold spread appears to continue as long as susceptible family members are present.[197] Infants born into households in which members are adenoviral fecal excreters often become infected, presumably through the fecal-oral route. In general, 50 percent of susceptible household members will experience infection, although the rate varies inversely with age and also depends on the serotype of adenovirus. Reinfection with specific adenoviral serotypes occurs, but most are asymptomatic or associated with only minimal illness.

Nosocomial spread of both respiratory and enteric adenoviruses is a common occurrence and has been the cause of fatal illnesses in infants and immunocompromised patients.‡

PATHOGENESIS AND PATHOLOGY

Adenoviral infections usually are acute and self-limited, and, therefore, opportunities to study the pathogenesis and pathologic process have been infrequent. Study of the pathologic mechanisms has been performed in human volunteers, tissue and organ culture systems, and recent murine model systems and by examination of specimens from persons dying of adenoviral disease.

Viral Infection

In general, the characteristics of adenoviral infection depend on the host and the serotype of the agent.§ The route of infection with adenoviruses that are capable of causing pharyngoconjunctival fever determines the pathologic manifestations. In most respiratory illnesses, initial viral infection occurs in the respiratory tract and involves the mucous membranes of the nose, oropharynx, and conjunctiva. Adenoviral agents have been isolated from sputum and oral secretions from 2 days before the onset of clinical illness to up to 8 days after the onset of symptoms. Deeper respiratory tract involvement of the trachea, pleurae, and lungs may result from initial small-particle aerosols, from progression of local infection, or perhaps as a result of viremia. Gastrointestinal infection in conjunction with respiratory tract infection also occurs early and probably is the result of swallowed virus. Stool isolates of respiratory viral types frequently are noted concomitantly with respiratory tract infection. However, in contrast to the upper respiratory tract infection, the virus may persist for a long time in the lower gastrointestinal tract. Infection with enteric adenoviral types is presumed to involve intestinal epithelial cells. In one fatal infection, adenoviral antigen was demonstrated in jejunal cells.[507,640]

In experimental studies with aerosolized adenovirus type 4, recovery of virus from throat specimens occurred on day 5 or 6, progressed to a maximum concentration on day 11 or 12, and was seen uncommonly after day 20. Maximal recovery of adenovirus type 4 from anal specimens occurred on day 13, and shedding continued for longer than 3 weeks. Adenovirus types 26 and 27 inoculated into the conjunctiva resulted in short-term isolation of virus from the eyes on days 3 to 7 and, less frequently, from the throat on day 4.[328] Isolation of virus from the rectum was common beginning at the end of the first week. Maximal fecal shedding occurred during the second and third weeks.

Viremia is a common finding in uncomplicated adenoviral respiratory tract infections in children. In a study involving 68 children, adenoviral DNA was noted in acute-phase serum samples from 28 (41%) of these children.[2] In the children with primary infection, 72 percent (21 of 29) had adenoviral DNA in their acute-phase serum samples. Other evidence of the presence of adenoviruses in the bloodstream early in disease is the occurrence of maculopapular, morbilliform, or petechial exanthems (or any combination of such rashes), as well as recovery of virus from multiple organs such as the brain, kidney, urinary bladder, lymphoid tissue, and liver and at postmortem examination.* The virus has been cultured from the mononuclear cells of heparinized blood.[15]

Coinfections

With the expanded use of direct fluorescent assays and PCR, investigators are discovering a common prevalence of coinfections of adenoviruses with multiple serotypes,[32] with other viruses[139,148,278,367,631] and with bacteria.[50] As technology is improving and made more available, the

epidemiology of coinfection, as well as its impact on disease, is becoming clearer.

PATHOLOGY

Early pathologic changes are observed in the epithelium of the respiratory tract. The severity of adenoviral involvement varies with the different serotypes. In tracheal organ cultures, growth of adenovirus type 7 was characterized by an initial focal cytopathologic effect at 100 hours that quickly progressed to involve the whole epithelium.[118] Frequently, the cilia of inclusion-bearing cells were noted to be intact. In contrast to the findings with adenovirus type 7, a type 12 strain resulted in only a mild cytopathologic effect on the organ culture system.[118]

Microscopic examination of autopsy material from patients dying of adenoviral pneumonia revealed a loss of cilia in the tracheal epithelium, proliferation of other respiratory epithelial cells, and the presence of intranuclear inclusions.* In severe pneumonia, total destruction along with necrotizing bronchitis, bronchiolitis, and pneumonia is observed (Fig. 155-1). Mononuclear cellular infiltration is seen, and hyaline membranes and necrosis are present. Cilia and goblet cells are absent, and muscle fiber bundles and elastic fibers are dispersed. Frequently, epithelial cells have a characteristic appearance with adenoviral infection. These infected cells are enlarged grossly and lose their nuclear membranes; the nuclear material has migrated into the cytoplasm.[496] Blood vessels show edema, separation of filaments in their walls, and, occasionally, thrombosis.[672]

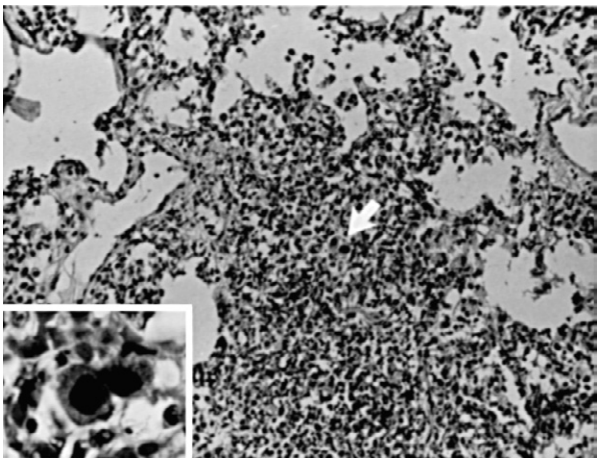

FIGURE 155-1 ■ The lung of a 17-month-old infant with adenoviral pneumonia. The infant died 10 days after the onset of illness, with no other contributing disease. The adenovirus isolated was not typed. A patchy pneumonia is present, and the *arrow* indicates two cells with nuclear inclusions. *Inset,* Two similar cells with typical adenoviral nuclear inclusions at higher magnification (hematoxylin and eosin stain, ×190; *inset,* ×770). (Courtesy Dr. David D. Porter, Department of Pathology, David Geffen School of Medicine at UCLA.)

*References 35, 45, 71, 91, 204, 644, 649, 651, 672.

In cases of pharyngoconjunctival fever, conjunctival biopsy specimens in volunteer studies revealed an inflammatory response with lymphocytic infiltration of the submucosal layer.[38,39] Biopsy material from palatine tonsils of infected volunteers revealed hypertrophy and hyperplasia of the lymphoid tissue, with congestion and edema of the surrounding connective tissue.

On histologic examination, adenoviral inclusions are characterized by small eosinophilic and larger basophilic intranuclear bodies.[35,204,449,561]

Hepatic involvement in adenoviral infection has been reported frequently.* In addition to isolation of virus from the liver, focal areas of liver necrosis accompanied by characteristic hepatic intranuclear inclusions have been demonstrated.[4,82,670] Electron microscopic examination has revealed adenoviral particles within the intranuclear inclusions.[4,45,496,644,670] Hematogenous spread to the central nervous system (CNS) has been observed.[551] Most patients with adenoviral CNS infection have had an associated pneumonia.[119,550] In CNS disease, the brain is edematous and congested. On microscopic examination, a perivascular accumulation of lymphocytes is noted, along with gigantic nuclear inclusions in the cortical neurons. Viral particles have been observed within these nuclear inclusions by electron microscopy.[103]

In epidemic keratoconjunctivitis caused by adenovirus type 8, the walls of the conjunctival vessels are damaged, and aneurysms are present. The surrounding conjunctival connective tissue is edematous. The virus has been suggested to penetrate the cornea along nerves deep into the epithelial layers in a manner similar to that occurring in herpes simplex virus (HSV) infection.[617]

Adenoviral strains have been isolated from, and intranuclear inclusions have been demonstrated in, renal tubular epithelium, lymph nodes, muscle, and gastrointestinal epithelium.†

Immunologic Events

The local response in adenoviral infection depends on the site of viral inoculation, the method of transmission, the viral serotype, the concentration of inoculum, and the antibody status of the host. Three days after infection develops, when virus can be recovered from the nasopharynx, marked transudation of proteins from serum into the respiratory tract occurs, along with the production of secretory IgA antibody.[411] Approximately 7 days after the onset of illness, serum-neutralizing, hemagglutination-inhibiting, and complement-fixing antibodies appear.[128,372,497] At the same time, the nasal secretions contain specific IgA and IgG antibody.[44] In general, neutralizing antibody is the most sensitive indicator of adenoviral infection, hemagglutination-inhibiting antibody is less sensitive, and complement-fixing antibody is the least sensitive.[348,474] Antibody titers peak in 2 to 3 weeks; complement-fixing antibody declines in 2 to 3 months but may persist for up to a year.[128,497] Neutralizing antibody persists for a longer period and is

*References 4, 20, 45, 82, 204 ,496, 558.
†References 42, 82, 640, 667, 668, 670.

measurable in many instances for periods as long as 10 years. Reinfection with the same adenoviral serotype is rare because of type-specific immunity.[39,525]

Although alterations in leukocytes are not common findings, a decrease in the number of lymphocytes has been observed before or at the onset of clinical illness and an increase in neutrophils occurs early in the disease, followed by a decrease later. Neutropenia may develop in severe disseminated illness and is attributed to a direct toxic effect of virus on leukocytes, marrow reserves, or both.[150] The erythrocyte sedimentation rate (ESR) of children has been normal or elevated to 55 mm/hr.[564,565]

Studies by Ginsberg and associates[227-229] in murine adenoviral pneumonia model systems noted that tumor necrosis factor-α (TNF-α), interleukin (IL)-1, and IL-6 were elaborated during the first 2 to 3 days of infection. However, only TNF-α played an early role in the initial phase of pathogenesis. The second phase of the inflammatory response is caused by the infiltration of cytotoxic T cells. In an extensive study, Kawasaki and colleagues[331] compared numerous clinical and laboratory test results in children with adenoviral infections with those in children with influenza and respiratory syncytial virus (RSV) infections. They found that the children with adenoviral infections had higher white blood cell (WBC) counts with a greater number of neutrophils than did children with influenza or RSV infections (12,322, 7,638, and 8,460 WBCs/mm,[3] respectively). The children with adenoviral infections also had more atypical lymphocytes and higher C-reactive protein (CRP) and ESR values. The mean serum IL-6 concentration was significantly higher in the children with adenoviral infections than it was in those with influenza and RSV infections (131.0, 26.7, and 15.0 pg/mL, respectively).

Mistchenko and coworkers[423] studied cytokines and adenovirus-specific circulating immune complexes in 38 children with adenoviral infections. They placed the patients into three groups based on the severity of their respiratory illnesses: moderate illness, severe illness, and fatal illness. Serum IL-1 was not detected in children with moderate illness but was found in 7 of 12 with severe illness and in 13 of the 16 children who died. TNF-α frequently was present in the sera of fatal cases, it was not present in the sera of moderately ill children, and it was detected in the sera of only 2 of 12 patients with severe but nonfatal illness. IL-8 was noted in all sera, but values were highest in children with fatal illness. Serum immune complexes (containing IgG) were found in 7 of the 16 children who died. Finally, patients with increased concentrations of IL-6, IL-8, and TNF-α were those with hypoperfusion, febrile peaks, seizures, and a manifestation of septic shock. Five of 10 children with severe or fatal illness had serum autoantibodies specific for smooth muscle.

Matsubara and associates[405] noted the participation of peripheral blood $CD8^+$ T cells and HLA-DR^+, $CD8^+$ T cells in children with adenoviral infection. One child with severe adenoviral type 7 pneumonia had a marked increase in HLA-DR^+ $CD8^+$ T cells, serum levels of interferon-γ, and peripheral blood interferon-γ–producing T cells.

CLINICAL MANIFESTATIONS

Adenoviral infections are exceedingly common events, and the spectrum of disease is quite broad. As noted in Table 155-3, some specific adenoviral diseases exist; however, the overall majority of infections involve a variety of anatomically associated illnesses. In many instances, similar illnesses are caused by other respiratory viruses and the clinical spectra of the various adenoviral serotypes frequently overlap. Certain specific adenoviral types do have clinical characteristics that facilitate etiologic diagnosis, however.

Respiratory Tract

Common Cold

Although adenoviruses frequently receive etiologic consideration in colds, they are, in fact, associated only rarely with this illness.[318] In one report, 3 percent of common colds in children were attributed to adenovirus,[488] and in another study, 6.4 percent of children with coryza had adenoviral isolates.[163] Respiratory tract infections with adenoviruses usually are associated with fever and, frequently, with some degree of pharyngitis; therefore, when strict clinical criteria are applied, they do not qualify as colds.[296,567] Occasionally, adenoviruses, particularly types 1, 2, 3, 5, and 7, have been recovered from patients with typical colds.

Nasopharyngitis, Pharyngitis, and Tonsillitis

Adenoviral pharyngitis is an acute illness characterized by fever, sore throat, extensive exudative tonsillitis, and, frequently, cervical adenopathy.[149,163,318,429,557] In two studies involving 74 children with adenoviral pharyngitis, Ruuskanen and associates[530] described the pharyngeal findings. Most commonly, only mild inflammation and redness were observed. When exudates were present, they found them to be thick and membranous, thin and follicular, or thin and spotty; most typical were follicular and spotty exudates. Associated symptoms include malaise, headache, myalgia, chills, and cough. In infants and preschool-aged children, nasal congestion and discharge are noticeable and abdominal pain is a common complaint.[603] Children with adenoviral acute febrile pharyngitis also frequently have laryngotracheitis, bronchitis, or pneumonia.[659] The usual duration of illness varies from 5 to 7 days, although occasionally, symptoms persist well into the second week.[530]

Acute febrile pharyngitis is the most common adenoviral illness in children and is particularly important as an epidemic illness in closed environments.[43,557,565,659] For example, in an epidemic in a children's home, 63 percent of the residents were infected with adenovirus type 7a.[257] Moffet and colleagues[429] noted that adenoviruses were the etiologic agents recovered most commonly from hospitalized preschool-aged children with febrile exudative pharyngitis; 23 percent of the children studied had adenoviral infections. In a university student health service study, 2.4 percent of illnesses with acute febrile pharyngitis were caused by adenoviruses.[442] Adenoviruses

TABLE 155-3 **Clinical Spectrum of Adenoviral Infections**

System/Organ	Illness Category	Epidemic Occurrence	Frequency	Adenoviral Type(s)
Respiratory	Common cold	No	Rare	1, 2, 3, 5, 7
	Nasopharyngitis, pharyngitis, and tonsillitis	Yes	Common	1,* 2,* 3,* 4, 5,* 7,* 7a, 14, 15, (21/H21+35)†
	Acute respiratory disease	Yes (in military recruits)	Very common	2, 3, 4,* 5, 7,* 8, 11, 14, 21
	Acute laryngotracheitis	No	Occasional	1, 2, 3, 5, 6, 7
	Acute bronchiolitis	No	Occasional	3, 7, 21
	Pneumonia (civilian population)	Yes	Common	1, 2, 3,* 4, 5, 7,* 7a,* 8, 11, 21,* (21/H21 + 35),† 35, 56
	Atypical pneumonia in military recruits	Yes	Common	4,* 7,* 21
	Pertussis-like syndrome	No	Rare	1, 2, 3, 5, 12, 19
	Bronchiolitis obliterans	No	Rare	2, 3, 7, 21
	Unilateral hyperlucent lung	No	Rare	7, 21
Eye	Acute follicular conjunctivitis	Yes	Common	1, 2, 3, 4, 6, 7, 8, 9, 10, 11, 15, 16, 17, 19, 20, 22, 31, 34, 37
	Pharyngoconjunctival fever	Yes	Common	1, 2,* 3,* 4,* 5, 6, 7,* 7a,* 8, 14,* 37
	Epidemic keratoconjunctivitis	Yes	Occasional	2, 3, 4, 5, 7, 8,* 10, 11, 13, 14, 15, 16, 17, 19, 23, 29, 37, 54, 56
Skin	Morbilliform and rubelliform exanthem	Rare	Occasional	3, 4, 7, 7a
	Roseola-like	No	Occasional	1, 2
	Stevens-Johnson syndrome	No	Rare	7
	Petechial exanthem	No	Rare	7

†Intermediate strain.

account for 37 to 75 percent of cases of nonstreptococcal pharyngitis in military recruits.

In children, 86 percent of cases of febrile pharyngitis are associated with adenovirus types 1, 2, 3, 5, and 7.[257,296,429]

On occasion, adenovirus types 7a, 9, 14, 15, and the intermediate strain 21/H21+35[277,557,565] also have been noted in association with pharyngitis. In military recruits, adenovirus types 4 and 7 are the main etiologic agents.

Acute Respiratory Disease

Acute respiratory disease is an epidemic disease that occurs predominantly in military recruit populations. This illness was studied extensively during World War II by the Commission on Acute Respiratory Diseases, and although individual cases were quite undifferentiated, the epidemiologic aspects of the outbreaks clearly indicated a specific etiologic agent.* The disease is an acute, febrile respiratory illness of short duration with constitutional and localized respiratory symptoms.[180] After an incubation period of 5 to 7 days, fever (mean temperature of 39.5° C [103.1° F]), pharyngitis, laryngitis, tracheitis, and a nonproductive cough develop.[52,126,226,482] The initial dry, hacking cough may progress to paroxysms. Malaise,

*References 27, 110, 226, 557, 570, 602.

myalgia, chills, headache, dizziness, rhinitis, conjunctivitis, abdominal pain, and local cervical lymphadenopathy are common complaints.[126] The inflammatory process may spread to the bronchi, the bronchioles, and the parenchyma of the lungs. In epidemics, as many as 67 percent of those affected wheeze and have other evidence of small airway obstruction; pneumonia occurs in 10 to 20 percent.[280,376,434] The illness gradually resolves over the course of an 8- to 36-day period.[202] Early in the illness, the total WBC count may be slightly elevated, with a small increase in the percentage of polymorphonuclear leukocytes.

In experimental, aerosol-induced acute respiratory disease the incubation period ranged between 6 and 13 days.[116] Typical illness included fever to 39° C (102.2° F), rhinitis, prostration, malaise, myalgia, and headache. Pneumonia occurred occasionally. The virus was recovered from throat culture specimens 5 days after inoculation, from the nose at 6 days, and after 9 days in fecal specimens. Serum-neutralizing antibody responses occurred between the third and fourth weeks. All ill volunteers had leukopenia and an elevated ESR during the illness.

The syndrome occurs most commonly in military recruits early in basic training; illness has been documented in as many as 90 percent of new trainees within the first 8 weeks of arrival at a training site.[280] The usual etiologic agents are adenovirus types 4 and 7. Occasionally, epidemics have been associated with adenovirus types 3, 11, 14, and 21,[68,199,580,620] and sporadic cases have been noted in connection with adenovirus types 2, 5, and 8.[280,482] The peak seasons of illness are winter and spring.[280]

Because of the magnitude of the problem of acute respiratory disease in military recruits, live attenuated adenoviral vaccines against types 4 and 7 were developed and used in all branches of the U.S. military beginning in the early 1970s.[31,240] These vaccines were used successfully until the early 1990s, when production delays occurred; subsequently, in 1995, the vaccine manufacturer stopped production. From 1999 through 2011, no vaccine was available, and epidemic disease returned to military training bases.* Although illness may occur in civilian adults, it is an uncommon event and not epidemic. In volunteer studies, subjects with serum antibody to a particular adenoviral type are protected against disease with that type of adenovirus induced by intranasal inoculation.[39,116]

Epidemic acute respiratory disease has not been described in children. However, a sporadic comparative illness, usually clinically identified as acute bronchitis, is commonly the result of adenoviral infection.[662] Adenovirus type 7 is the etiologic agent most frequently found in these cases.

Acute Laryngotracheitis

On occasion, adenoviruses have been implicated as a cause of acute laryngotracheitis. In general, the croup caused by adenoviruses is not severe and often is manifested only as a barking, brassy cough. Laryngotracheitis frequently is seen in association with febrile pharyngitis, bronchiolitis, and pneumonia.[597] Epidemics have not been observed. Adenovirus types 1, 2, 3, 5, 6, and 7 have been implicated as etiologic agents.

Acute Bronchiolitis

Adenoviruses account for 5 to 18 percent of cases of bronchiolitis in infants.[215,649] In a recent study of 143 children with adenoviral infections, the admitting diagnosis was bronchiolitis in 24 percent.[516] The bronchiolitis caused by adenoviral infection is sporadic and usually similar to illness associated with other viral agents. Occasionally, adenoviral bronchiolitis occurring early in infancy has been fatal or has resulted in serious residual lung damage and chronic disease.[637] This severe illness has been associated with serotypes 3, 7, and 21.

Pneumonia

Young Children. Adenoviruses are common isolates in children with pneumonia. The overall frequency of adenoviruses as a cause of nonbacterial pneumonia in children is less than that of RSV and parainfluenza virus type 3, but an alarming number of fatal illnesses have been noted. Severe and fatal illnesses in infants and young children have occurred in association with adenovirus types 1, 2, 3, 4, 5, 7, 7a, 7h, 7i, 8, 19, 21, 35, and the intermediate strain 21/H21+35.* The more severe cases of pneumonia have been linked to types 3, 7, and 21.[78,222,552,579,651] Adenoviral pneumonia has been epidemic and sporadic.[84,91,100,170,379]

Severe pneumonia occurs most commonly in neonates and young children aged 3 to 18 months.† The onset of illness is acute, with persistent cough and fever (>39° C). On physical examination, moderate to severe dyspnea is apparent, as is the associated tachypnea. Inspiratory and expiratory wheezes and rales are heard on auscultation. Other signs and symptoms include lethargy, diarrhea and vomiting, pharyngitis, and, occasionally, conjunctivitis. Extrapulmonary complications that occur commonly are meningitis, encephalitis, seizures, splenomegaly, hepatomegaly and hepatitis, myocarditis, nephritis, bleeding tendency, and exanthems.‡ Chest radiographs reveal diffuse infiltrates, which usually are bilateral and may be bronchial, peribronchial, or interstitial.[35,362,516,645] Hyperinflation and lobar collapse occur frequently.[232] Rarely, pleural effusions or mediastinal lymphadenopathy has been described.[362] In surviving infants, symptoms persist for 2 to 4 weeks and radiographic changes resolve slowly, frequently being present at the 3-week follow-up examination.[91,100,552] Recovery often is gradual, and exacerbations occur commonly.[305,480]

Serious sequelae often result from adenoviral lower respiratory disease, particularly in association with

*References 68, 351, 528, 531, 580, 620.

‡References 45, 71, 91, 112, 362, 550, 552, 561, 564.

adenovirus types 3, 7, 7a, and 21.* Such sequelae include bronchiectasis, bronchiolitis obliterans, and unilateral hyperlucent lung.† An estimated 14 to 60 percent of children with documented adenoviral lower respiratory tract disease have some degree of permanent pulmonary sequelae.[232,362,551,552] In a study of 27 children conducted 10 years after they had documented adenoviral type 7 pneumonia, 12 had radiographic evidence of bronchiectasis or residual pulmonary changes; 16 children had abnormal results on pulmonary function studies.[551]

Macek and associates[395] have suggested that persistent adenoviral infection may be the cause of chronic obstructive airway disease in children. They noted adenoviral antigen in bronchoalveolar lavage specimens from 31 of 34 patients with chronic disease but in no bronchoalveolar specimens from a control group.

On occasion, severe and fatal adenoviral pneumonia has been related to malnutrition, environmental crowding, or a preceding severe viral disease such as measles.‡

Severe adenoviral pneumonia associated with adenovirus types 3 and 7 also has been reported occasionally in previously healthy adults.[485,495,555] One adult had severe pneumonia caused by adenovirus type 21 that was associated with myalgia, rhabdomyolysis, and myoglobinuria.[652]

Atypical Pneumonia in Military Recruits. Seven to 20 percent of cases of pneumonia in military recruits are associated with adenoviral infection.[73,196,219] Primary atypical adenoviral pneumonia commonly occurs in the winter months and generally is caused by adenovirus types 4, 7, and 21.[196] The illness is associated with fever, cough, sore throat, rhinorrhea, and chest pain. Other common symptoms include nausea, vomiting, myalgia, headache, and diarrhea. On physical examination, rales and pharyngitis are present in almost all cases. Rhinitis and generalized lymphadenopathy are observed in approximately half of those afflicted, and, occasionally, conjunctivitis is noted. Chest radiographs reveal a bilaterally mottled appearance, most prominent in the lower lobes; they remain abnormal for 4 to 36 days.[73] Although serum cold agglutinins are observed, titers of 1:32 or higher are detected in only 18 percent of patients.[73,219]

Fatal pneumonia, absolute leukopenia, and disseminated disease have been reported in four previously healthy military trainees. Adenovirus type 7 was the etiologic agent in three of these cases, and the fourth illness was caused by adenovirus type 4.[156,376]

Pertussis-like Syndrome. A pertussis-like illness has been noted in association with several adenoviruses, including types 1, 2, 3, 5, 12, and 19.[109,111,257,452,466] The illness occurs commonly in children younger than 36 months. The onset of illness is insidious and initially suggestive of a cold. The cough becomes progressively worse and, by 1 to 2 weeks, is paroxysmal. Severe recurrent episodes of paroxysms result in the production of mucus, posttussive fatigue, and vomiting.[111] Approximately 50 percent of children have a typical whoop, and cyanosis occurs with the paroxysms. Peripheral leukocytosis with WBC counts ranging from 25,000 to 125,000 cells/mm^3 along with lymphocytosis and thrombocytosis is the usual finding.[109,466] The recovery time ranges from 4 to 10 weeks from the onset of illness.[111] Radiologic evidence of bronchiolitis is present in most children; interstitial pneumonia occurs occasionally. In our opinion, most and probably all of these pertussis-like illnesses are indeed *Bordetella pertussis* infections in which adenovirus is a coinfecting agent (see Chapter 129). In young infants, coinfection (adenovirus plus *B. pertussis*) may lead to more severe disease.[37,378,407]

Bronchiolitis Obliterans. Bronchiolitis obliterans is a chronic bronchiolitis that initially was described in 1901 by Lange.[363] It has been noted to occur after measles, influenza, and pertussis, as well as after the inhalation of toxic substances.[25,36,649] Adenovirus types 2, 3, 7, and 21 have resulted in a bronchiolitis obliterans–type chronic illness.* These adenoviruses cause a severe necrotizing bronchiolitis that heals with fibrosis and predominantly obliterates the small airways.[31] The onset of disease is characterized by an acute febrile illness, cough, and respiratory distress. Disease may wax and wane for several weeks or months and is associated with recurrent episodes of atelectasis, pneumonia, and wheezing. Although some children recover from these episodes, the remainder have chronic pulmonary disease, including irreversible atelectasis, bronchiectasis, or hyperlucent lung syndrome.[36,637,649]

Castro-Rodriguez and colleagues[83] conducted a 5-year follow-up study of 38 children hospitalized with adenoviral pneumonia during an outbreak in Santiago, Chile, in 1998. Bronchiolitis obliterans developed in almost 50 percent of these children. Nosocomial acquisition of adenoviral infection was found to be associated more significantly with the development of bronchiolitis obliterans than community-acquired infection was. Murtagh and colleagues conducted a retrospective review of 415 children with lower respiratory tract infection caused by adenoviruses. The found that risk factors for the development of bronchiolitis obliterans included prolonged hospitalization (>30 days), multifocal pneumonia, and hypercapnia.[441]

Unilateral Hyperlucent Lung. Unilateral hyperlucent lung is a well-defined syndrome characterized by increased translucency of all or part of one lung, along with a reduction in lung size.[121,396] The unilateral hyperlucency is associated with a decrease in the size and number of pulmonary vessels, as observed on pulmonary angiograms, and an absence of peripheral filling at bronchography.[396] Although the disease may have a number of causes, including pneumonia secondary to other viruses, it has been noted to occur after severe necrotizing bronchiolitis and pneumonia caused by adenovirus types 7 and 21.[396,649]

Eye

Acute Follicular Conjunctivitis

Acute follicular conjunctivitis is the most common and benign of the adenoviral infections of the eye. The

*References 25, 36, 83, 177, 232, 305, 362, 552.
†References 25, 36, 83, 177, 362, 396, 426, 491, 552, 649.

infection in this disease is confined to the eye, generally is unilateral, and is manifested by follicular lesions on the palpebral conjunctival surface. Symptoms occur after an incubation period of 5 to 7 days and include lacrimation, itching, burning, a foreign body sensation, and conjunctival erythema.[141] Although the preceding symptoms increase the likelihood of viral infection, rather than a bacterial infection, the diagnosis by clinical symptoms alone can be difficult to make.[461] Examination shows erythema and lymphoid follicular hyperplasia in the conjunctiva in association with serous drainage and increased lacrimation. Occasionally, adenopathy of the preauricular lymph nodes is seen. Symptoms resolve in 10 days to 3 weeks, with recovery usually complete.[115,141] Adenovirus types 1, 2, 3, 4, 6, 7, 8, 9, 10, 11, 15, 16, 17, 19, 20, 22, 30, 31, 34, and 37 have been isolated from the eyes of afflicted patients.*

Pharyngoconjunctival Fever

By definition, pharyngoconjunctival fever is a syndrome characterized by fever, pharyngitis, and conjunctivitis. During epidemics, not all patients have the complete syndrome triad. For purposes of this discussion, all descriptions of frequency of signs and symptoms are calculated from the starting point of 100 percent fever, pharyngitis, and conjunctivitis.

Tables 155-4 and 155-5 summarize the frequencies of specific symptoms and signs.† The usual onset of illness is abrupt, with sore throat, generalized aches and pains, eye irritation or pain, and fever. Throat complaints vary from mild to severe. On examination, the tonsils and pharyngeal lymphoid tissue are hypertrophied with pharyngeal redness varying considerably from patient to patient. Approximately one third of affected patients have follicular exudative lesions that cannot be differentiated from streptococcal disease on clinical grounds. Hypertrophy of the adenoids occurs, which may result in nasal blockage. Coryza and posterior nasal discharge are common, leading to cough in many instances.

With respect to conjunctivitis, most patients note some aching or soreness; photophobia and lacrimation are unusual. The appearance of the palpebral conjunctiva usually is granular. The lesions may be almost microscopic or 2 to 3 mm in diameter. Hemorrhages occasionally are noted on the bulbar surface. Frequently, involvement starts in one eye and does not involve the other eye until 2 or 3 days later. Occasionally, the involvement is restricted to one eye.

Compared with other viral respiratory tract infections, the duration of illness with pharyngoconjunctival fever is long. In most patients, the fever is sustained or remittent for 3 to 4 days; however, approximately 10 percent of patients have fever that lasts longer than 7 days. Throat and eye findings usually are improved considerably by the seventh day of illness, but these findings and nasal complaints, fatigue, and headache may persist for 14 days.

In epidemic pharyngoconjunctival fever, the most likely etiologic agent is adenovirus type 3.* The next most prevalent adenovirus associated with epidemic disease is type 7.[77,159,194,658] One or more epidemics also have been noted with adenoviruses 2, 4, 7a, 11, and 14.† Sporadic occurrences of pharyngoconjunctival fever have been observed in association with infections with adenoviruses 1, 2, 3, 4, 5, 6, 7, 7a, 8, 14, 19, and 13/30 (an intermediate type).‡

Epidemic Keratoconjunctivitis

Epidemic keratoconjunctivitis is caused most commonly by adenovirus type 8, but it also has resulted from infection with adenovirus types 2, 3, 4, 5, 7, 10, 11, 13, 14, 15, 16, 17, 19, 22, 23, 29, and 37.§ Currently, adenovirus type

37 is the virus most commonly recovered from patients with epidemic keratoconjunctivitis in the United States and Europe. The most severe disease is associated with adenovirus types 5, 8, and 19.[125] More recently in Japan, adenovirus types 54 and 56 have been recovered from patients with epidemic keratoconjunctivitis.[10,302]

The illness occurs most commonly in adults, but a few cases have been reported in children.[258,428,577] It has no seasonal pattern. Although transmission of the viral agent from the respiratory tract to the eye occurs in sporadic cases, the usual method of viral spread is by contaminated ophthalmic instruments and eye solutions, hand-to-eye contact by medical personnel and others, swimming pools, or hands or fomites in close-contact situations, such as in families and in industry.* The incubation period typically is 5 to 10 days but ranges from as short a period as 2 days to as long as 2 weeks.[127,348] The initial symptom generally is unilateral, acute, follicular conjunctivitis that suggests the presence of a foreign body. Photophobia, lacrimation, discharge, hyperemia, and edema of the conjunctiva are notable. Preauricular adenopathy occurs in as many as 90 percent of patients, and 50 percent of those afflicted have pharyngitis and rhinitis. Spread to the other eye may occur in 2 to 7 days. Seven to 10 days after onset of the disease, the conjunctivitis resolves, and painful, superficial, punctate epithelial opacities appear in the center of the cornea. These lesions frequently extend subepithelially and then heal, with subepithelial infiltrates left behind that may persist for months. In severe cases, hazy vision may continue for several years.[29]

An infantile form of epidemic keratoconjunctivitis has been described that usually affects children younger than 2 years old.[169] This pseudomembranous or membranous conjunctivitis generally is accompanied by high fever, pharyngitis, otitis media, diarrhea, and vomiting. Preauricular lymphadenopathy typically is absent.[577]

Virus can be recovered from the eye for a usual period of approximately 2 weeks but has been detected for 2 to 3 years in patients with chronic papillary conjunctivitis.[125,490] In acute illness, conjunctival scrapings obtained during the first 10 days of infection reveal characteristic inclusion bodies when stained with Giemsa.[268] Virus-specific fluorescent antibody staining is diagnostic in epidemic keratoconjunctivitis.[541] Preparations of corneal and conjunctival epithelia reveal adenoviral particles when examined with the electron microscope.[132]

Skin

Adenovirus types 1, 2, 3, 4, 7, and 7a, plus several unknown types, have been noted in connection with exanthematous disease.[96] The cutaneous manifestation most commonly associated with adenoviral infection is an erythematous maculopapular rash that appears while the child is febrile. In many instances, children with this illness have been thought to have either measles or rubella.[358] In most adenoviral infections with exanthems, other clinical findings more characteristic of adenoviruses, such as conjunctivitis, rhinitis, pharyngitis, and lymphadenopathy, also are present. In some instances, the exanthem truly is morbilliform with a characteristic confluence, but Koplik spots do not occur.

A widespread erythematous rash often is present early in the course of severe pneumonia in infants.[232] Chany and colleagues[91] noted a measles-like rash in five patients who died of adenovirus type 7a pneumonia. One report describes a child with an adenovirus type 7 infection and illness suggestive of meningococcemia.[532] This patient had fever, vomiting, diarrhea, and a petechial exanthem. Rocholl and associates[516] noted that rash occurred in 10 percent of 143 adenoviral illnesses in children.

On several occasions, illness characterized by fever and defervescence and then the appearance of a maculopapular rash suggesting the diagnosis of roseola infantum has been observed.[193,207,307,308,453] Adenoviral infections also are confused with rubella. However, the respiratory symptoms and the degree of fever associated with adenoviral infection should clarify the diagnosis. With rubella, respiratory complaints and fever are minimal. On occasion, severe disease with Stevens-Johnson syndrome has been noted. Such patients frequently have pneumonia, and the illness is quite similar to that caused by *Mycoplasma pneumoniae*.

Lähdeaho and associates[361] have noted that serum antibodies to the E1b protein–derived peptides of the

*References 29, 76, 87, 125, 127, 130, 192, 309, 348, 404, 428, 430, 577, 635.

enteric adenovirus type 40 are associated with dermatitis herpetiformis.

Genitourinary Tract

Acute Hemorrhagic Cystitis

Acute hemorrhagic cystitis is an uncommon manifestation of adenoviral infection in immunocompetent children and is characterized by a sudden onset of dysuria and frequency, with hematuria developing 12 to 24 hours later.* Occasionally, fever, suprapubic pain, and enuresis occur. Antecedent upper respiratory tract infection is noted in some children. Symptoms persist for a few days to 2 weeks, with the usual duration being approximately 5 days. Acute hemorrhagic cystitis has been reported in both the United States and Japan. It occurs primarily in children, most often boys, and usually is associated with adenovirus type 11. Occasionally, adenovirus types 7 and 21 have been implicated. Adenoviral antigen has been identified by immunofluorescence in exfoliated bladder cells. Although no sequelae have been reported, the long-term prognosis is unknown.[435]

Nephritis

Hematuria occasionally has been reported in infants with severe pneumonia and disseminated adenoviral infection. Red blood cells and, at times, red blood cell casts also have been noted in the urine of some children with upper respiratory tract infections caused by adenoviruses and specifically in patients with pharyngoconjunctival fever associated with adenovirus types 3, 4, and 7a.[557,562,603,607] In one instance, a young boy had a maculopapular and petechial exanthem and thrombocytopenia associated with adenovirus type 7 infection. Hematuria also was present.

Orchitis

Orchitis developed in one child who had a 5-day history of pain and fever, erythema, and swelling of the right testis.[451] The testicular involvement resolved in several days, and the illness was associated with a 16-fold rise in adenoviral complement-fixation antibody titer.

Oculogenital Syndrome

In 1977, Laverty and associates[368] reported a woman who in addition to pharyngoconjunctival fever had cervicitis and paresthesia of the legs; a type 19 adenovirus was recovered from this woman's cervix. In Perth, Australia, adenovirus type 19 was recovered from the genital tracts of 59 men and women being examined for genital HSV infection in a clinic for sexually transmitted diseases.[301] Several of the patients also had conjunctivitis, and in two patients adenovirus type 19 was isolated from conjunctival specimens. Similar oculogenital illnesses have been noted in association with adenoviral types 2, 8, and 37.[86,536,573]

*References 368, 369, 400, 435, 436, 459.

Hemolytic-Uremic Syndrome

Hemolytic-uremic syndrome in association with adenoviral infection has been described in two 2-year-old children.[51]

Hemorrhagic Fever with Renal Syndrome

An adenovirus type 11 infection associated with hemorrhagic fever with renal syndrome has been reported in a 22-year-old woman.[599]

Gastrointestinal Tract

Gastroenteritis

Infantile diarrhea has been associated with epidemic and sporadic adenoviral diseases such as acute upper respiratory tract infection, severe pneumonia, and pharyngoconjunctival fever.[193,362,557,566,640] Outbreaks of diarrhea characterized by acute abdominal pain followed by diarrhea, nausea and vomiting, fever, headache, and pharyngitis have been associated with adenovirus type 3 and 7 infections.[217,565] Other symptoms occurring in patients with diarrhea include conjunctivitis, rhinitis, pharyngotonsillitis, hepatomegaly, and cervical adenitis.[566] In two patients who had diarrhea and upper respiratory tract illness in association with adenovirus type 15 infection, viral particles were visualized within the nuclei of mucosal cells at autopsy by electron microscopy.[157]

The widespread use of electron microscopy for the study of rotaviral diarrhea led to the finding of previously unrecognized adenoviruses that were fastidious and could not be grown in routine cell cultures.[432,540] These adenoviruses, now identified as types 40 and 41, subsequently were shown to be important causes of gastroenteritis in children.* In enteric adenoviral infection, diarrhea is the most prominent symptom.[596] In children with adenovirus type 40 infection, Uhnoo and colleagues[597] found that the mean duration was 8.6 days, as opposed to 12.2 days in those infected with adenovirus type 41. Most illnesses occur in children younger than 3 years old: the mean age for adenovirus type 40 diarrhea was 15.2 months, whereas it was 28.3 months in type 41 illnesses. Most patients had mild vomiting that lasted approximately 2 days. When compared with illnesses caused by established respiratory adenoviruses, fever occurred less commonly, was less severe, and had a shorter duration in enteric adenoviral infections. Upper respiratory tract symptoms and signs, such as pharyngitis, coryza, cough, and otitis media, were observed in 21 percent of children with enteric adenoviral infection. Brandt and colleagues[64] noted that dual infections with respiratory viruses (such as RSV and enteric adenoviruses) are common occurrences, so caution should be observed in attributing respiratory symptoms to enteric adenoviruses.

Yolken and Franklin[664] found that enteric adenoviruses were an important cause of nosocomial diarrhea in infants

*References 65, 69, 104, 143, 144, 233, 354, 356, 424, 464, 474, 517, 584, 597, 610.

who had previously undergone gastrointestinal surgery for necrotizing enterocolitis.

Mesenteric Lymphadenitis

Adenoviral serotypes 1, 2, 3, 5, and 7 have been recovered from lymph nodes and the appendix in cases of mesenteric lymphadenitis.[42,56,346] Patients with mesenteric lymphadenitis often have abdominal pain and other symptoms similar to those of acute appendicitis. Pharyngitis is a frequently related finding. Mesenteric adenitis often is associated with concurrent or recent adenoviral illness.[112,501] Frequently, the peak incidence of mesenteric lymphadenitis occurs when adenoviral illness is common in the community.

Intussusception

The suggestion that adenoviruses could be an etiologic factor in intussusception arose because these agents frequently can be recovered from throat, stool, and mesenteric lymph node specimens obtained from children who undergo surgery for intussusception.* Most children with intussusception were younger than 2 years old; some had preceding respiratory symptoms.[523,667] Adenovirus serotypes 1, 2, 3, 5, 6, and 7 have been implicated. Typical adenoviral intranuclear inclusions have been demonstrated in cells in stool, intestinal epithelia (ileum), and the appendix by electron microscopy.[460,667,668] Mesenteric lymph nodes often are enlarged at surgery.[668] Increases in antibody titer to adenoviruses have been observed in children after the development of intussusception. Investigators have suggested that bowel wall hypermotility caused by direct viral involvement or by hypertrophy of lymphatic tissue is the lead point for the intussusception.†

Appendicitis

Adenoviruses have been associated with both acute and chronic appendicitis.[56] Right iliac fossa abdominal pain in conjunction with sore throat is a common finding. The virus has been isolated from the appendix and mesenteric lymph nodes at surgery. During acute infection, lymphoid follicles of the ileum, appendix, and mesenteric lymph nodes are infected with virus. In chronic infection, adenovirus remains in cells; on microscopic examination, slight inflammation is seen in the appendix.

Hepatitis

Hepatitis in association with adenoviral infection has been reported many times in small infants, in children with overwhelming disseminated disease, and in immunocompromised patients.‡ In one study, 27 of 30 persons thought to have sporadic infectious hepatitis were found to be infected with adenovirus type 5.[259] Adenovirus types 1, 2, and 3 were isolated from the stool specimens of 12 children younger than 3 years old in an outbreak of infectious hepatitis on an American Indian reservation in Arizona.[261]

In one report, three children with severe, fatal adenovirus type 7 pneumonia had associated findings that simulated Reye syndrome: lethargy, diarrhea, seizures, elevated CSF pressure, myocarditis, hepatitis, and disseminated intravascular coagulation.[360] Edwards and colleagues[162] reported three children with Reye syndrome and adenoviral infection. They suggested that adenoviruses might be an important agent in initiating the syndrome.

Heart

Myocarditis

In children, myocarditis has been noted in association with severe pneumonia and disseminated disease caused by adenovirus types 7, 7a, and 21.[264,269] Similar cardiac involvement has been seen in military recruits with severe acute respiratory disease.[91,100,264,557] One case of sudden death in an 11-year-old boy due to myocarditis with adenovirus type 3 has been documented.[590]

The use of polymerase chain reaction (PCR) assays has led to recognition of adenovirus as the cause of many cases of acute myocarditis.[58,66,246,394,403] In an extensive study of myocarditis and dilated cardiomyopathy, Bowles and coworkers[58] analyzed 773 endomyocardial biopsy samples obtained from patients of all ages. In this large group, 624 patients had myocarditis and adenoviral DNA was identified by PCR in 142 (23%) of the endomyocardial biopsy samples. There were 26 neonates, 37 infants, 20 toddlers, 25 older children, 11 adolescents, and 23 adults. The results of this study suggest that adenoviruses are the leading viral cause of myocarditis, with enteroviruses being the second most common association (14%). On histopathologic examination, only 57 (40%) of the enterovirus-positive samples were found to be acute myocarditis.

Dilated Cardiomyopathy

In the study by Bowles and associates,[58] specimens from 149 patients exhibited dilated cardiomyopathy. Of this subgroup, 18 (12%) had adenoviral DNA demonstrated by PCR in the endomyocardial biopsy specimen. Of these 18 samples, 2 were from neonates, 2 from infants, 2 from toddlers, 4 from older children, 2 from adolescents, and 6 from adults. In a study in adults, 28 explanted hearts from patient undergoing transplant for dilated cardiomyopathy yielded adenovirus type 3 in 25 percent of cases by nested PCR.[581]

Pericarditis

Pericarditis has been associated with severe adenoviral pneumonia. In a patient with adenovirus type 7 pneumonia, electrocardiographic changes consistent with pericarditis were demonstrated and the virus was isolated in high titer from pericardial fluid at postmortem examination.[449] In 1995, Mistchenko and coworkers[425] reported a 10-month-old boy with fatal pericarditis caused by adenovirus type 7. In serum and pericardial fluid from this

*References 42, 48, 107, 216, 294, 460, 495, 523, 667, 668.
†References 42, 107, 216, 460, 498, 523, 667, 668.
‡References 4, 20, 45, 71, 82, 342 ,670.

child, IL-6, TNF-α, and adenovirus-specific immune complexes were identified.

Nervous System

Although CNS disease in adenoviral infection is an uncommon finding, a variety of clinical manifestations have been observed. Both meningitis and encephalitis have been noted as the major manifestations of adenoviral infection or in association with severe disease at other body sites.[457,462] Adenovirus types 1, 2, 3, 5, 6, 7, 12, 26, and 32, in isolated instances, have been recovered from both brain and CSF.* Meningoencephalitis often occurs as part of disseminated adenoviral disease in immunocompromised patients, with the most commonly associated serotypes being 2, 3, 5, and 7. Adenovirus serotype 26 DNA was identified in peripheral blood, CSF, urine, and postmortem brain tissue of a 28-year-old woman undergoing radiation therapy for medulloblastoma; progressive neurologic deterioration developed, followed by her eventual death as a result of disseminated adenoviral infection.[152] In two children with respiratory and CNS symptoms, adenoviruses were recovered from CSF.[181] One child was convalescing from herpes zoster and the other from varicella. Adenovirus type 7 was recovered from brain tissue cultures from an elderly patient with chronic schizophrenia.[393] In another instance, adenovirus type 32 was recovered from the brain of a man with lymphosarcoma and subacute encephalitis.[103,520] In an epidemic of adenoviral infection caused by type 7, 25 percent of the hospitalized patients had symptoms referable to the CNS.[550,552] Many of the patients died; those who survived had little residual effect. Too few cases are reported in the literature to predict the prognosis of CNS disease in children accurately. Adenovirus type 2 was isolated from a muscle biopsy specimen from a patient with inclusion body myositis.[421] Ooi and colleagues[467] reported eight children with adenovirus serotype 21–associated acute flaccid paralysis in the setting of an enterovirus 71–mediated hand-foot-and-mouth disease outbreak in Sarawak, Malaysia, in 1997. Of these eight children, four had upper limb monoparesis, two had lower limb monoparesis, and two had paraparesis. Four of the children experienced complete recovery, one was improving at hospital discharge, and three had residual flaccid weakness and wasting. Seven children with initially appearing typical adenoviral infections had transient encephalopathy.[568] All these children were infected with adenovirus type 3. On initial evaluation, five had pneumonia, one had follicular tonsillitis, and one suffered from diarrhea. Three of the children were lethargic, two were stuporous, and two were obtunded. All had elevated serum aspartate aminotransferase values (range, 39 to 401 U/L), and CSF evaluations were within normal limits. The neurologic findings resolved in all patients in about 1 week.

Infection in Immunocompromised Hosts

Adenovirus types 1, 2, 3, 4, 5, 6, 7, 7a, 11, 29, 31, 32, 34, and 35 have been recovered from children and adults who were immunocompromised by immunodeficiency diseases, malignancies, corticosteroid therapy, immunosuppressive therapy, radiation therapy, and transplantation procedures.* Adenoviral infections occur more frequently in pediatric than in adult hematopoietic stem cell and solid-organ transplant recipients.[28,285,293] Infection is thought to occur as a result of transmission from the donor, reactivation of latent infection, or newly acquired infection.[357] McLaughlin and colleagues[412] examined the incidence of adenovirus infection in 146 children who underwent liver and intestinal transplants. They found that adenoviral infection occurred in 4.1 percent of liver transplant recipients and 20.8 percent of intestinal transplant recipients.

In a study of eight children with liver and small bowel transplants and six with just small bowel transplants, Pinchoff and coworkers[494] noted that all had evidence of adenoviral infection of the graft. In eight of the children, histologic evidence of infection (adenoviral intranuclear inclusions) developed, and these eight had received intensive corticosteroid therapy, had virus isolated from multiple sites, and had persistent positive viral cultures. In a retrospective review of 110 small bowel and liver (combined) transplants in 98 children by Florescu and colleagues, adenovirus infection was found in 38 transplants. Twenty-three of these developed invasive disease, and over 80 percent occurred within the first year of transplant. In this series, the presence of adenovirus did not have an effect on all-cause mortality.[190] For most solid-organ transplants, the source of invasive adenoviral disease often is thought to be the transplanted organ.

Kampmann and colleagues[325] conducted a prospective study on 155 pediatric stem cell transplant recipients and identified 17 percent with adenoviremia (26/155). Their study showed that early detection of adenoviremia, withdrawal of immunosuppression, and early antiviral therapy led to resolution of adenoviremia in 81 percent of the patients. de Mezerville and collaborators[138] retrospectively identified 28 solid-organ transplant recipients and 27 hematopoietic stem cell transplant recipients with adenovirus infection at the Hospital for Sick Children in Toronto, Canada. Their study found a similar rate of posttransplant adenoviral infection in solid-organ transplant recipients (50.9%) and hematopoietic stem cell transplant recipients (49.1%). de Mezerville's group found a much higher mortality rate in the group of hematopoietic stem cell transplant recipients (30% mortality rate vs. 0% in the solid-organ transplant group). Using PCR, Bil-Lula and colleagues reviewed adenovirus infection in 116 patients (98 children, 18 adults) who underwent stem cell transplant. Infection was found in 52 patients (44.8%). Although overall mortality in infected patients was 19 percent, this did not differ significantly from that in uninfected patients.[49,166]

Control of adenovirus infection is thought to be T cell mediated, and patients receiving T cell–suppressive regimens are thought to be at greater risk for adenovirus

*References 93, 112, 119, 152, 181, 213, 334, 478, 489, 520, 564, 571, 606.

*References 4, 28, 34, 79, 82, 103, 124, 129, 179, 184, 189, 218, 243, 250, 262, 271, 321, 333, 384, 392, 442, 455, 463, 479, 494, 520, 545-548, 553, 558, 592, 616, 644, 663, 670.

disease.[636] Myers and colleagues[443] demonstrated an increased risk for development of adenoviral infection in bone marrow transplant recipients receiving alemtuzumab (Campath 1H), a monoclonal antibody used for T-cell depletion, in comparison with patients receiving antithymocyte globulin, which was composed of polyclonal antibodies directed toward T cells. Avivi and colleagues[24] demonstrated that the most important risk factors for progression of adenovirus disease included severe lymphocytopenia (absolute lymphocyte count < 200/mm^3) and continued immunosuppression. They also found a correlation between lack of prophylaxis with ganciclovir for cytomegalovirus infection and risk for progression of adenovirus disease.

Ahmad and coworkers[8] reported a case of severe adenovirus pneumonia developing after infliximab (Remicade) was used to treat a 35-year-old man with Crohn disease. Infliximab is a monoclonal antibody directed against TNF-α that is used frequently in the treatment of autoimmune and rheumatologic diseases. Ahmad's group emphasized the fact that TNF-α antagonists can impair cell-mediated immunity, an essential component of recovery from adenoviral infection in immunocompromised hosts, and, therefore, can predispose patients to the development of viral pneumonia.

Other groups have demonstrated that having low lymphocyte counts at the time of development of adenovirus infection was predictive of adenovirus viremia and that clearance of infection and host survival were dependent on recovery of adenovirus-specific CD4$^+$ T-cell responses.[262,612,636] Lankester and colleagues[365] showed that isolation of adenovirus from multiple sites was associated with the development of adenovirus disease. Lins' group[383] demonstrated an association between isolation of adenovirus in peripheral blood and progression or dissemination (or both) of adenovirus disease. High levels of adenovirus viremia (i.e., detection of PCR product at 100-fold or greater dilution of template DNA) have been correlated with fatal outcomes in children receiving allogeneic stem cell transplants.[537,611]

Baldwin and colleagues[28] studied the outcome and clinical course of 105 adenoviral infections in 100 patients after they received bone marrow transplants. The incidence was higher in unrelated donor transplants than in matched sibling donor transplants. Diarrhea and fever were the most common initial findings. Six deaths were attributed to the adenoviral infections; five of the six patients had pneumonia, and four had associated graft-versus-host disease. Three additional patients had severe disease.

In a study involving 532 recipients of hematopoietic stem cell transplants, a 12 percent incidence of adenoviral infection was noted.[293] Forty-one patients had infections classified as "invasive," and mortality was 76 percent in this group. Recipients of allogeneic transplants were more likely than autologous stem cell recipients to have adenoviral infections.

The most common manifestation of adenoviral infection in pediatric patients with bone marrow transplants at St. Jude Children's Research Hospital was hemorrhagic cystitis, followed by gastroenteritis, pneumonitis, and liver failure.[190] Adenovirus-induced acute hemorrhagic cystitis is a complication encountered after hematopoietic stem cell transplantation and, more rarely, after renal transplantation.[185,286] Gorczynska and colleagues[236] examined the incidence of virus-induced hemorrhagic cystitis in 102 children and adolescents who underwent allogeneic stem cell transplantation. Hemorrhagic cystitis occurred in 25.5 percent of these children, with 3.9 percent of the cases attributed to adenoviruses. Another retrospective review of 266 adults undergoing stem cell transplant showed the incidence of adenoviral hemorrhagic cystitis to be 9.8 percent. Increased risk for cystitis was linked with underlying disease (cancer other than acute leukemia) and with T-cell purging with antithymocyte globulin or alemtuzumab. Patients with acute graft-versus-host disease had a decreased incidence of hemorrhagic cystitis.[431]

Shirali and coworkers[547] noted that demonstration of the adenoviral genome in endomyocardial biopsy specimens from heart transplant recipients was a predictor of graft loss in children. Graft loss with concomitant adenovirus infection has been described in renal transplant patients.[352,355] Scattered reports have found an association between adenoviral infection and viruria and hemorrhagic cystitis in patients with renal transplants.[187,363] Fatal and severe cases of subacute meningoencephalitis caused by an adenovirus have been described in bone marrow transplant recipients.[129,203] Severe necrotizing pneumonia with pulmonary hemorrhage due to adenovirus in a lung transplant patient has been described.[408]

In many instances, a fulminant, bacterial, sepsis-like picture with high fever, cough, and lethargy is associated with adenoviral infection in compromised patients.[670] Severe pneumonia often is demonstrated, both clinically and radiologically, and hepatic involvement with disseminated intravascular coagulation also is a frequent occurrence. Fatalities are reported, and recovery often is slow.

Other Manifestations

Arthritis

Arthritis has been noted in association with adenovirus type 7 infection.[476] The illness was characterized by fever, acute respiratory symptoms, erythematous macular rash, aseptic meningitis, and inflammatory arthritis of both knees.

Thyroiditis

In 1964, Swann[572] reported five patients with acute thyroiditis and thyroid enlargement in whom serologic study revealed greater than fourfold rises in titer of adenoviral complement-fixing antibody.

Deafness

Deafness of sudden onset was reported in an adult with a 2-day history of sore throat, low-grade fever, rhinorrhea, and cough. Adenovirus type 3 was isolated from the patient's throat, and a greater than fourfold rise in neutralizing antibody titer to this virus was observed.[304]

Obesity

Studies have shown that exposure to human adenovirus serotype 36 is associated with increased adiposity in chickens, mice, and nonhuman primates.[145-147] Continuing work in mouse models showed that adenovirus 36 infection increased macrophage infiltration into adipocytes[447] and impairs insulin signaling, thus altering glucose metabolism.[313] Paradoxically, reduced serum cholesterol and serum triglycerides are seen in the same animal models. Atkinson and colleagues[22,613] proposed that adenovirus serotype 36 directly affects adipocytes by increasing the number and size of preadipocytes. Vangipuram and associates[614] explored the possible mechanisms by which adenovirus types 36 and 37 increase adiposity in animal models. They performed ex vivo experiments in human adipocytes and a murine preadipocyte cell line (3T3-L1) and in vivo experiments in the rat model, which demonstrated suppression of leptin mRNA expression, decreased leptin secretion, and increased glucose uptake. In vitro studies have shown that adenovirus 36 infection causes upregulation of adipogenesis-related genes, along with inflammation which lead to lipid accumulation in cells.[446] Fatty acid oxidation was also shown to be impaired in in-vitro models.[632]

Based on studies that adenoviruses increase adiposity in animal models, Atkinson and coworkers[22] screened 502 subjects for neutralizing antibodies to adenovirus 36. They detected antibodies to adenovirus 36 in as many as 30 percent of obese study subjects as opposed to 11 percent of nonobese subjects. Similarly, they found paradoxically decreased serum cholesterol and triglycerides in patients with antibodies to adenovirus 36. Subsequent studies have shown mixed results. Several studies have shown a correlation between seropositivity to adenovirus 36 and obesity.[21,23,212,593] In a study of adults, Na and associates[445] showed that although seropositivity to adenovirus 36 did correlate with overweight body mass index (BMI) (23 to 25), this relationship did not hold when examining obese individuals (BMI >25). A study completed in Holland and Belgium by Goossens and colleagues[235] in active-duty U.S. military personnel[67] failed to show correlations between adenovirus 36 seropositivity and BMI. Interestingly, Trovato and colleagues showed that adenovirus 36 seropositivity was correlated with greater decrease in BMI and reduction of insulin resistance when subjects were placed on diet and exercise programs.[594] One study has shown increased serum cholesterol and triglycerides in children with antibodies against adenovirus 36.[444] Additional studies by Whigham and colleagues[638] demonstrated that human adenovirus serotype 37 also is associated with an increase in adipocyte differentiation and reduced serum triglyceride levels but increased serum cholesterol levels.

Congenital and Neonatal Infections

Neonatal and congenital adenoviral infections reflect disseminated infection with the involvement of multiple organs.* Major manifestations include hepatosplenomegaly, progressive pneumonia, hepatitis, and thrombocytopenia. Towbin and colleagues[589] reported intrauterine adenoviral myocarditis manifested as nonimmune hydrops fetalis. Illnesses frequently appear initially as an early-onset sepsis syndrome. An infant has been reported with a congenital pleural effusion from which type 3 adenovirus was recovered.[419]

Couroucli and associates[117] noted an association between adenoviral infection and bronchopulmonary dysplasia. A significant increase was found in the frequency of adenovirus genome in tracheal aspirates from patients with bronchopulmonary dysplasia versus control subjects.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of adenoviral infection must be subcategorized on the basis of the major clinical manifestations. In many instances, specific clinical symptoms such as pharyngoconjunctival fever or epidemic keratoconjunctivitis can lead to strong suspicion of the adenoviral etiology. With other, more general respiratory diseases such as pharyngitis, bronchitis, croup, bronchiolitis, and pneumonia, the adenoviral etiology cannot be established on clinical grounds. Fever in adenoviral respiratory tract infections tends to be higher than that occurring in parainfluenza and RSV infections but is similar to that in influenza A and B viral infections.[502] High and prolonged fever occurs as commonly in adenoviral infections as it does in bacterial respiratory tract infections. Because the symptom triad of fever, pharyngitis, and conjunctivitis is virtually unique to pharyngoconjunctival fever, establishing the diagnosis of this disease should be easy. Generalized diseases that occasionally might be confused with pharyngoconjunctival fever include leptospirosis, psittacosis, *Mycoplasma pneumoniae* infection, Q fever, Newcastle disease virus infection, and prodromal measles.

In pharyngitis, adenoviral infection must be differentiated both from other viral diseases, such as those caused by Epstein-Barr virus, parainfluenza and influenza viruses, and enteroviruses, and from streptococcal disease. In a young child, follicular pharyngitis is more likely to be caused by adenoviral than by streptococcal infection.

Adenoviral pneumonia in young children frequently is not distinguishable on clinical grounds from that caused by bacteria. In older children and adolescents, in particular, adenoviral pneumonia often can be differentiated from bacterial disease by its bilateral nature. Differentiating adenoviral illness from disease caused by *M. pneumoniae* is more difficult; however, cold agglutinin titers generally are higher and more persistently positive in mycoplasmal disease.

Adenoviral eye disease must be differentiated from that caused by viruses of the herpes group, enteroviral epidemic conjunctivitis (acute hemorrhagic conjunctivitis),[382,660,661] and *Chlamydia* spp., and bacteria, including *Neisseria gonorrhoeae*.

Diarrhea caused by enteric adenoviruses can be differentiated from other viral diarrheas by electron microscopy, by identification with ELISA, and by specific culture of the enteric agents in Graham 293 cell culture. Enteric bacterial and parasitic agents also must be considered in the differential diagnosis.

*References 3, 70, 101, 177, 344, 469, 564.

The high, relatively prolonged fever occurring in association with lymphadenopathy, exanthem, and enanthem noted with adenoviral infection often causes confusion with Kawasaki disease.[95,516] Because Kawasaki disease must be treated early with intravenous immunoglobulin, adenoviral infections should be considered early and appropriate studies performed.

DIAGNOSIS

Adenoviral infection can be diagnosed specifically by isolation of virus in an appropriate tissue culture system, direct antigen detection assay, or by DNA PCR. Most adenoviral types can be recovered from clinical specimens in primary or diploid cultures of human embryonic kidney.[373] The enteric viral types 40 and 41 can be grown in Graham 293 cells.[576,625] The rapidity of detection of adenoviruses by culture is enhanced by centrifugation of specimens in shell vials or plastic-welled plates.[158,171,397]

Direct identification of adenoviruses in respiratory secretions by radioimmunoassay, immunofluorescence techniques, and ELISA now is performed widely.* However, in general, the sensitivity, when compared with that of virus isolation, is relatively low; on the other hand, the specificity is high (>95%). Rocholl and colleagues[516] demonstrated the impact of rapid diagnosis of adenoviral respiratory disease with an adenoviral direct fluorescent antibody technique by noting discontinuation of empirical antibiotic use in a retrospective analysis of hospitalized patients with respiratory cultures positive for adenovirus. Rapid techniques for the identification of enteric adenoviruses in general have been sensitive and specific.† However, in newborns, false-positive results with a latex agglutination test have been reported.[300] Several techniques using DNA probes have been studied for the rapid identification of both respiratory and enteric adenoviral infection.[75,299,575] PCR assay also is useful for the rapid detection of adenoviral infection and is rapidly becoming the gold standard of diagnosis alongside tissue culture isolation.‡ PCR assay is particularly useful for identifying adenoviral DNA in formalin-fixed, paraffin-embedded tissues and other biopsy and postmortem specimens.§

Several groups have demonstrated the utility of PCR detection of adenoviral DNA in acute respiratory tract infections in immunocompetent patients.[2,178,516,546,656] Kuypers and colleagues[359] demonstrated significantly increased sensitivity of quantitative real-time PCR assay over fluorescent antibody detection of adenoviruses. They showed that 77.7 percent of respiratory specimens that were negative for adenovirus by fluorescent antibody detection were positive by PCR detection of adenovirus DNA. This increased sensitivity was replicated by Stroparo and colleagues.[569] Multiple PCR assays have been developed to detect multiple serotypes of adenovirus.[383,656] Buckwalter and colleagues developed real-time PCR for qualitative detection of all 57 serotypes of adenovirus with high sensitivity and specificity in a variety of clinical samples.[74] Others have demonstrated similar multiplex assays for adenovirus, although they were narrower in scope.[470] Aberle and colleagues[2] were able to detect adenoviral DNA with a nested PCR assay in acute-phase sera collected within the first week after the onset of symptoms in 72 percent of immunocompetent children experiencing their first adenoviral infection and in 25 percent of those experiencing recurrent infection.

Other groups have demonstrated the utility of using PCR assays to diagnose and monitor adenoviral infection and disease in immunocompromised hosts.[365,537] Lion's group[385] developed a species-specific, real-time, quantitative PCR assay that allows detection and quantification of 51 human adenovirus subtypes. They showed that detection of adenovirus DNA in the peripheral blood of allogeneic bone marrow transplant recipients preceded the onset of clinical symptoms of disseminated adenoviral disease by a median of 3 weeks. Two other groups[374,628] have used real-time, quantitative PCR assays to detect adenoviral DNA load to aid in both the diagnosis and management of disseminated adenoviral infections in immunocompromised patients. Ebner and colleagues[160] recently have presented a two-stage PCR algorithm for diagnosis in immunosuppressed patients. Although algorithms for detection and typing of adenoviruses have been used in the past,[160,410] the use of type-specific PCR and other techniques such as reverse-line-blot has made serotyping more efficient.[74,80]

Multiplex PCR to detect multiple different viruses in a clinical sample (e.g., respiratory secretions, stool, blood) are now becoming widely available. Commercial, as well as "home-made" assays can now test for up to 13 different viruses with fast turnaround (1 to 4 hours) and excellent sensitivity and specificity.* The availability of inexpensive, reliable, and fast PCR kits has raised the question of whether the detection of viral genetic material can be attributed to true infection or shedding of dead virus from a past event. Kalu and colleagues[324] showed in a cohort of 76 children with 581 episodes of upper respiratory tract infection that adenoviruses of the same type and strain would persistently be detected by PCR in nasopharyngeal washes of the same host for over 200 days. The authors caution that clinical interpretation of PCR test results is necessary, because most practitioners do not have access to phylogenetic analysis. At present, most hospitals rely on fluorescent antibody staining, shell vial culture, and viral culture to identify adenovirus infection. Multiplex PCR, especially for the diagnosis of respiratory viral illness, as well as singleplex adenovirus PCR is quickly taking the place of these methods.

Acute infection also can be diagnosed serologically by the expression of specific serum IgM antibody.[418] Infection can be confirmed serologically by the demonstration of a rise in antibody titer in two sequential serum samples. Antibody response to the adenovirus group antigen can be detected by complement fixation or ELISA.

Type-specific antibodies can be determined by neutralization, ELISA, or hemagglutination inhibition.

TREATMENT

During the febrile period of illness, adequate hydration should be maintained and excessive activity discouraged. The fever may be controlled with acetaminophen. In children with eye involvement, careful attention should be paid to the possibility of secondary bacterial infection. If local purulence develops, specimens should be procured for culture and topical antimicrobial therapy started. The use of corticosteroid-containing ophthalmic ointments should be avoided.

A consistent, safe, and effective therapy to treat adenovirus infection has yet to be established. Although vidarabine, ribavirin, and cidofovir demonstrate good activity against adenoviruses in vitro, several studies have shown only limited success with the use of vidarabine, ribavirin, ganciclovir, and cidofovir in treating adenovirus disease in humans.[387,438] The potential beneficial effects must be weighed carefully against the adverse side effects of these antiviral agents, including myelosuppression, pancytopenia, and nephrotoxicity. Walls and coworkers[629] conducted a retrospective study of 26 patients undergoing hematopoietic stem cell transplantation. They were unable to demonstrate a direct correlation among adenoviral DNA load, clinical features, and severity of disease. They also identified two children who experienced low-level adenoviral viremia after undergoing hematopoietic stem cell transplantation; in these children the viral infection resolved without treatment. Williams and colleagues created an algorithm to risk-stratify pediatric oncology and stem cell transplant patients with adenovirus infection to determine who would benefit from cidofovir therapy without uneccesary risk for nephrotoxicity. They determined high-risk patients to be those with recent transplant (<60 days allogeneic or <180 days autologous), those with graft-versus-host disease, and those on immunosuppressive therapy. These patients would benefit from cidofovir, whereas those without these risk factors would do well without treatment. Their algorithm was validated in a small prospective cohort of 11 patients.[647]

Ribavirin is a guanosine nucleoside analog used for the treatment of severe RSV infection in its inhaled form and for the treatment of chronic hepatitis C infection. In a number of instances, immunocompromised patients with disseminated adenoviral infection have been treated with ribavirin administered intravenously and successful outcomes have been reported.* In one instance, a loading dose of 30 mg/kg/day divided into three doses was followed by maintenance therapy with 15 mg/kg/day.[409] Gavin and Katz[218] reported complete clinical recovery in two of five patients with severe adenovirus disease. A later study by Lankester and associates[364] demonstrated no effect on plasma adenoviral DNA load despite initiation of treatment with ribavirin at the first onset of clinical symptoms in four pediatric patients receiving allogeneic stem cell transplants. Intravenous ribavirin is available in the United States only as an emergency investigational drug because it is not approved by the U.S. Food and Drug Administration. Data on its use, efficacy, and safety are still very limited.[513]

The antiviral agent with the most promise to date is cidofovir, a cytosine nucleoside analog with efficacy against several DNA viruses, including cytomegalovirus, HSV, polyomaviruses, and adenoviruses. Cidofovir was used successfully in treating a 17-year-old boy who had received a stem cell transplant and had severe adenoviral gastroenteritis.[510] Ljungman and colleagues[388] conducted a study of cidofovir for the Infectious Diseases Working Party for Blood and Marrow Transplantation (EMBT). They demonstrated successful treatment of adenovirus infections in 69 percent of allogeneic hematopoietic stem cell transplant recipients, primarily with a 5-mg/kg dose of cidofovir given intravenously one time per week for the first 3 weeks and every other week after that, along with concomitant use of probenecid and intravenous fluid hydration. Other studies have shown a similar effect with reduced dosing of cidofovir at 1 mg/kg per dose given three times a week.[260,387,438] A case report by Fanourgiakis and colleagues[179] demonstrated successful treatment of severe (grade IV) hemorrhagic cystitis in a 34-year-old man by intravesical instillation of 5 mg/kg of cidofovir in 100 mL saline twice daily. This method avoided the known nephrotoxicity associated with cidofovir. Saquib and colleagues reported on two adult renal transplant patients with adenovirus viremia successfully treated with cidofovir along with intravenous immune globulin, and concurrent reduction in immune suppressive therapy. [535] Yusuf and coworkers[669] reported complete resolution of clinical symptoms in 57 of 58 pediatric hematopoietic stem cell transplant recipients treated with cidofovir. Wallot and colleagues[627] had some success using reduced-dose cidofovir, inhaled nitric oxide, and decreased immunosuppression to treat two liver transplant recipients with disseminated adenoviral disease and acute respiratory distress syndrome. CMX001 (hexadecyloxypropyl-cidofovir) is a new antiviral drug made by Chimerex and is a lipid conjugate of cidofovir. It has broad activity against double-stranded DNA viruses in vitro and is currently undergoing clinical trials to treat adenovirus infections as well as BK polyoma virus, vaccinia, and molluscum contagiosum.[99] Evaluation of treatment of poxviruses in mouse models is also ongoing.[151]

Paolino and colleagues were the first to report successful recovery from disseminated adenovirus infection in a pediatric stem cell transplant patient using CMX001 after treatment failure with cidofovir.[477]

Florescu and colleagues retrospectively reviewed salvage treatment of adenovirus infection with CMX001 (after failure with cidofovir) in 13 solid-organ and stem cell transplant patients: 9 patients had a significant lowering of viral load, whereas 4 patients did not. The former group did have a statistically longer survival time, and no patients discontinued treatment owing to drug side effects.[191]

Further studies into possible immunotherapies for the treatment of adenovirus infections also have been investigated. Feuchtinger and associates[186] were able to perform successful and safe adoptive transfer of

*References 17, 326, 381, 409, 440, 513, 654.

adenovirus-specific, T-cell immunity in five of six patients with documented adenovirus infection after allogeneic hematopoietic stem cell transplantation. This effect was found to be independent of the T-cell dose. Furthermore, the adenovirus-specific, T-cell expansion was sustainable and proliferation of the adenovirus-specific T cells was unimpaired by adenovirus viremia, in contrast to the myelosuppressive effects seen with cytomegaloviral viremia. Currently, emphasis of study is on the efficient and effective in vitro manufacturing of cytotoxic T lymphocytes for use in immunocompromised individuals.[9,206,220,549,671]

Teuchner and colleagues[582] studied *N*-chlorotaurine (NCT), a compound produced by monocytes and granulocytes during the oxidative burst, in a double-blind investigation of adult patients with epidemic keratoconjunctivitis. Among the group of 60 patients, 33 were treated with a 1 percent aqueous solution of NCT and 27 were treated with gentamicin. These researchers analyzed both subjective and objective scores. In the total study group, the NCT-treated subjects were subjectively better than the gentamicin-treated patients at day 8, but there were no objective differences. However, in severe infections, both the subjective and objective scores were better on days 4 and 8 in the NCT-treated patients. They concluded that NCT treatment was well tolerated and that it shortened the duration of illness. A study of the use of 1 percent cidofovir eyedrops with and without 1 percent cyclosporine eyedrops to treat adenovirus-associated keratoconjunctivitis was conducted by Hillenkamp and colleagues.[283] This study demonstrated significant local toxicity in the skin of the eyelids and conjunctiva but a decreased frequency of severe corneal opacities associated with the use of cidofovir. A novel drug, NVC-422 has shown good in vitro activity against adenovirus. This compound is an analog of NCT that has been modified to gain better stability in solid-state solution. A phase 2 clinical trial for adenoviral conjunctivitis is ongoing.[666]

Human fibroblast–derived interferon, applied topically, was used to treat epidemic adenoviral keratoconjunctivitis in a comparative trial.[519] The duration of illness was reduced in the patients treated with interferon, but many of the control patients received dexamethasone. A child with combined immunodeficiency and severe, diffuse adenovirus type 7a pneumonia improved dramatically after receiving a large dose of high-titer adenovirus type 7a immune serum globulin.[124]

PREVENTION

Serious incapacitating epidemics caused by adenoviruses in military recruits in basic training led to the development of adenoviral vaccines.[16,371] The initial vaccines were formalin-inactivated preparations of virus grown in monkey kidney tissue culture and were administered parenterally.[15,245,280] These vaccines achieved only limited success because of variable degrees of potency in different vaccine lots.[36] An inactivated adenoviral vaccine that contained types 3, 4, and 7 was prepared in monkey tissue culture for trial in children.[608] Three doses of this vaccine resulted in high levels of neutralizing antibody to the three viral types, and this antibody persisted in most infants for at least 1 year. Many of the initial lots of inactivated adenoviral vaccine were found to contain live simian adenoviruses that were capable of producing neoplasms in suckling hamsters. Because of this finding, inactivated vaccine trials were discontinued. Next, a live, attenuated adenovirus type 4 vaccine that was cultivated in human diploid tissue culture was developed and administered orally by enteric-coated capsule to volunteers.[586,587] Asymptomatic gastrointestinal infection occurred, and a good serum-neutralizing antibody response was elicited.[245,556,560] Most recipients of live oral vaccine excrete virus in stool for several days to a month after being vaccinated. With military use of the vaccine, shedding in stool was not associated with transmission of the virus to nonimmune contacts.[434] In other studies of married couples and families with children, virus was transmitted to nonimmune contacts.[434,561] Transmission usually occurred without illness.[434]

The administration of live, enteric-coated, type 4 and 7 adenovirus vaccine resulted in a significant decrease in the incidence of acute respiratory disease in military recruits.[155,234,574] In 1995, this vaccination program was terminated, and the last stocks of vaccine were depleted or expired by 1999. However, after a subsequent rise in the incidence of acute respiratory disease and deaths in military servicemen,[29,240,351,531] vaccination was resumed. A new live oral vaccine for type 4 and 7 human adenoviruses is now licensed and in use since 2011.[598] Few attempts have been made to protect children with live adenoviral vaccines. In one study, live enteric-coated adenovirus type 4 vaccine was given to children aged 5 to 11 years. Asymptomatic gastrointestinal infection resulted from administration of the vaccine. Because the major cause of pharyngoconjunctival fever caused by adenoviruses is swimming in contaminated water, discretion in bathing locations is advised. Swimming pool water should be chlorinated adequately, and pool filtration systems should be inspected daily. Ill individuals should be excluded from swimming pools during their illness and for at least 2 weeks after recovery.

PROGNOSIS

The overall prognosis of adenoviral infection generally is excellent. Secondary bacterial complications, if untreated, can result in prolongation of illness and permanent sequelae in some instances. The prognosis of adenoviral infection in the very young and in immunocompromised patients must be guarded.

DNA VIRUSES

SUBSECTION 4 *HEPATOVIRIDAE*

CHAPTER 156

Hepatitis B and D Viruses

Maureen Jonas • Janis Stoll

HEPATITIS B VIRUS

Hepatitis B virus (HBV) infection occurs throughout the world, although marked geographic differences in rates of both acute and chronic infection exist. An estimated 360 to 400 million individuals (approximately 5% of the world's population) are infected.[68,87,119] In the United States the total number of persons with chronic hepatitis B is estimated at 2 million.[44,78] People chronically infected with HBV are at risk for developing cirrhosis and hepatocellular carcinoma (HCC). Worldwide mortality is estimated at 0.5 to 1.2 million deaths per year.[123] Most of those with chronic HBV infection acquired the virus through vertical transmission, which can now be prevented in the majority of cases by active and passive immunization.

BIOLOGY

HBV is the prototype of a family of DNA viruses called *hepadnaviruses* (hepatotropic DNA viruses). This group consists of enveloped, coated, double-stranded DNA viruses with similar structure and genome organization.

All primarily infect the livers of their respective hosts and can cause acute and chronic infections. HBV is the most studied member of the family, which also includes the woodchuck hepatitis virus (WHV), the ground squirrel hepatitis virus, the duck hepatitis virus (DHV), and hepatitis viruses found in herons, Ross's geese, and arctic squirrels.[178] The WHV and DHV share approximately 70 percent sequence homology with HBV but do not infect humans.[182] The use of these animal models has facilitated the study of hepadnavirus structure and replication, supplementing information obtained from infected humans and cloning studies.

Three types of particles are found in the sera of HBV-infected people and are shown in Figure 156-1: the Dane particle and two subviral particles, one spherical and the other filament shaped. All three types share a common surface antigen, hepatitis B surface antigen (HBsAg), but only one, the Dane particle, contains viral DNA and is capable of replication. Neither the filament, 20 nm in width and ranging from 50 to 1000 nm in length, nor the sphere, also of 20 nm diameter, contains nucleic acid. The Dane particle or whole virion is 42 nm in diameter and contains a core, or nucleocapsid, enclosing the DNA. The outer shell is composed of large amounts of hepatitis B surface proteins in a lipoprotein envelope, which is derived from host cells. Inside this shell is found the nucleocapsid, an icosahedral structure composed of 240 core protein subunits with regular penetrating channels. The nucleocapsid proteins are detected serologically as hepatitis B core antigen (HBcAg). This nucleocapsid is 25 to 27 nm in diameter, and within it are contained the viral genome and polymerase. HBV e antigen (HBeAg) is a soluble antigen produced from the same open reading frame as is HBcAg, but, unlike core antigen, e antigen is secreted into serum, where it is thought to have a role in induction of tolerance to HBV. The viral genome is composed of double-stranded circular DNA that can be relaxed or closed depending on the stage in the reproduction cycle. This 3.2-kb DNA encodes four overlapping open reading frames (ORFs) that overlap with other regulatory *cis*-acting sequences such as promoters, enhancers, and polyadenylation and genome packaging signals.

The subviral particles (spheres and filaments) are composed of envelope proteins and host-derived lipid components.[178] These particles are abundant in the serum of infected individuals (10^6 to 10^{14} particles/mL), and they are highly immunogenic, stimulating the production of neutralizing antibodies. One hypothesis is that they absorb neutralizing antibodies, thus shielding the intact virion from the host immune response. Subviral particles were used to produce the first effective HBV vaccine.[203]

Molecular Virology

The viral genome, as noted previously, contains four ORFs in its circular DNA. The DNA strands are not completely symmetric; the minus strand is shorter, leading to a region of single-stranded DNA. This gap can be filled by the virus's own polymerase when required. The four genes are *S* for the surface or envelope gene; *P* for the viral polymerase gene; *C* for the core gene, which encodes nucleocapsid protein; and *X* for the X gene. The surface proteins synthesized by HBV are termed the

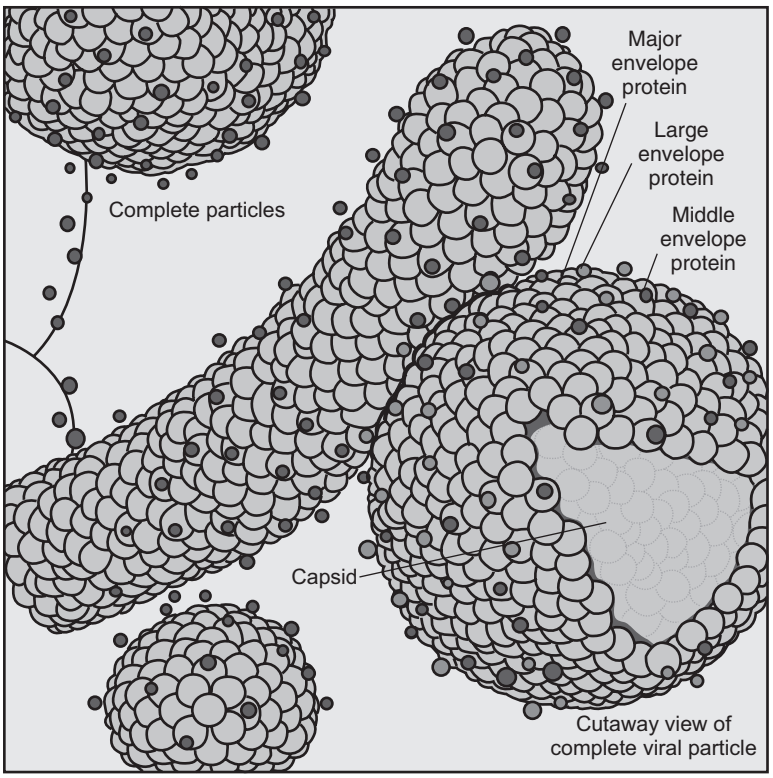

FIGURE 156-1 ■ The three forms of HBV surface antigen are whole virions, rods, and proteins. A cutaway view of the whole virion shows the three envelope proteins: major, middle, and large. (From Mutchnik MG. Acute and chronic hepatitis B. In: Feldman M, Maddrey WC, editors. *The liver.* Philadelphia: Current Medicine; 1996.)

large, *middle*, *and major proteins;* they are type II transmembrane proteins that can form multimers. Transcription initiated at the *pre-S1*, *pre-S2*, or *S* epitopes leads to formation of these three proteins. Although antibodies to S protein alone will provide protection against HBV infection, epitopes of *pre-S1* also can stimulate neutralizing antibody production.[120] A group of antigens used for subtyping HBV strains in epidemiologic studies is found in association with S proteins. Analysis of subdeterminants of HBsAg has revealed four major serotypes, *adw*, *adr*, *ayw*, and *ayr*, thus allowing differentiation of HBV infections from different sources. The "a" determinant is found in all isolates. Antibody to hepatitis B surface antigen (anti-HBs) is directed against this determinant and provides protection against all serotypes.

Eight HBV genotypes and multiple subgenotypes have been identified by use of polymerase chain reaction (PCR)–restriction fragment length polymorphism analysis of the complete viral genome.[105,130] They have been designated A through H. Genotypes B, C, and D have been further categorized into five subgenotypes each (HBV B1 to B5, HBV C1 to C5, and HBV D1 to D5).[140,176] Genotype and subgenotype predominance varies by geographic location: A study of 187 patients with chronic HBV infection revealed the following marked regional variations in genotype: North Europeans, 63 percent A; South Europeans and Middle Easterners, 96 percent D; Africans, 53 percent A, 27 percent D, 20 percent E; East Asians, 14 percent A, 43 percent B, and 43 percent C.[130] The clinical differences among HBV genotypes are being elucidated. Infection with genotype C was found in Taiwanese adults to be associated with more severe liver disease and HCC in those older than 50 years of age, whereas genotype B is associated with HCC in younger persons.[104] In a study of 487 Chinese HBV-infected children, genotype C was more common (76.4%) than genotype B (22.3%) or genotype D (1.3%). Children with chronic HBV B2 had less severe inflammation and fibrosis than those with HBV C2.[228] An association of genotype with response to interferon-α (IFN-α) treatment also has been demonstrated. A study from Taiwan analyzed the responses of 58 patients with chronic HBV infection genotypes B and C to treatment with IFN-α. The patients with genotype C had higher aminotransferase levels at baseline. After 48 weeks of follow-up, only 15 percent of those with genotype C were HBeAg negative and HBV DNA negative, as compared with 42 percent of those with genotype B.[106]

HBV polymerase consists of two major domains tethered by an intervening spacer region. Elucidating the structure and biochemistry of hepadnavirus polymerases has proved difficult because they require cellular factors, which are lost during extraction from cells, for enzymatic activity.[156] The ORF that encodes the *P* gene overlaps to a large extent with the core protein ORF; indeed, both proteins are translated from the same mRNA.[32]

The core gene encodes the viral capsid proteins that combine to form the core particles. The core proteins combine first into dimers; 120 dimers unite to form a shell 36 nm in diameter.[47] HBcAg appears to be phosphorylated within cells and becomes dephosphorylated upon export.[196] The main role of core proteins is enclosure of viral DNA, but they also play a role in the cytolysis of infected cells when expressed on the cell surface.[127] Mutations in the core gene, the pre-core region, and the promoter for *C* have become clinically important.

Mutations affecting all ORFs of the HBV genome have been described. Most viral genomes carry more than one mutation, and most individuals are infected with more than one variant. Some of the mutations are thought to contribute to viral latency, level of infection, severity of liver disease, and vaccine escape. The group best studied is the pre-core mutants, which result in lack of HBeAg production, even in the presence of active viral replication, the so-called HBe antigen–negative infection. In contrast to the situation in persons with wild-type virus, in whom absence of HBeAg usually signifies absent HBV replication and mild liver disease (see later discussion), in HBeAg-negative hepatitis, HBV DNA levels are high, antibody to hepatitis B e antigen (anti-HBe) is detected, and liver disease may be severe. Sporadic cases and outbreaks of fulminant HBV infection have been attributed to pre-core mutants. Mutations in the *S* or *pre-S* gene, which encode envelope protein, have been reported in patients infected after vaccination and in individuals who received monoclonal antibody to HBV after liver transplantation. This variant contains a missense mutation in the *a* determinant of the surface antigen. Subsequently, these mutants were demonstrated in chronic HBV carriers even without these immune pressures. This mutation causes an infection in which HBsAg is undetectable but in which HBeAg and HBV-DNA are found, in contrast to the typical serologic pattern (see later discussion).

The role of X protein is not fully understood, but it is required for establishment of infection in vivo although not for transfection of cells in vitro.[16,42] X protein is a regulatory protein involved in transcriptional activation during viral replication[127]; it has also has been shown to transactivate the promoters of other viruses such as human immunodeficiency virus (HIV) and human T-lymphotropic virus type 1.[172] In addition, hepatitis B X protein appears to be involved in the development of HCC.[13]

Viral Life Cycle Overview

Like retroviruses, hepadnaviruses replicate by means of reverse transcription of an RNA intermediate[200] (i.e., the flow of genetic information is from DNA to RNA to DNA). As shown in Figure 156-2, after the virus binds to receptors on the cell surface, virion nucleocapsids are delivered to the cytoplasm, where they translocate to the nucleus. There the genomic DNA is converted to the covalently closed circular DNA (cccDNA) form that serves as a template for the reverse transcription. This cccDNA is transcribed by host RNA polymerase II, and the resulting RNAs are translated to originate the *P*, *C*, *S/pre-S*, and *X* gene products. The viral pol initiates encapsidation of viral pregenomic RNAs into the cytoplasm by binding to the 5′ encapsidation signal, epsilon, on the pgRNA.[137] Through a series of complex host-viral interactions, negative strand DNA synthesis is

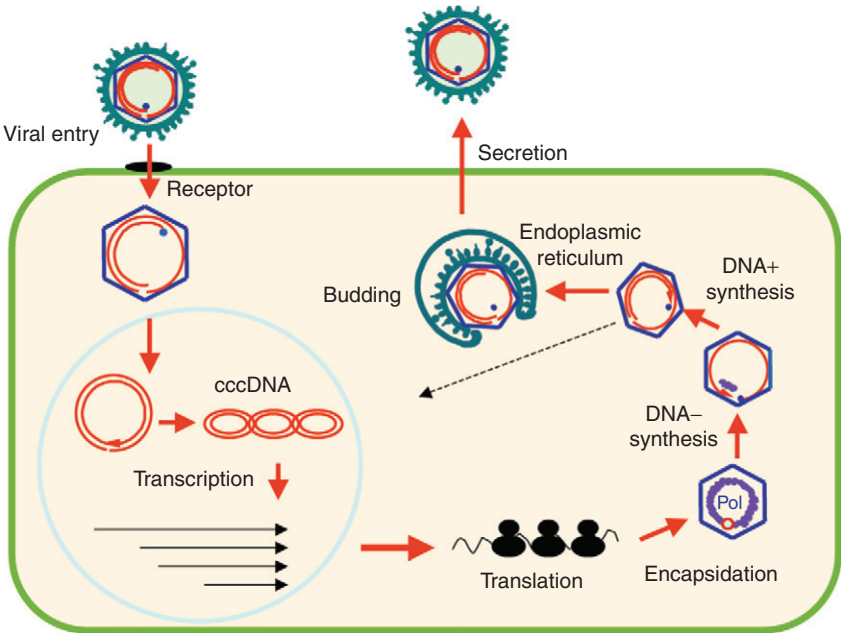

FIGURE 156-2 ■ The virus enters the cell through a receptor or receptors, and the viral genome is imported into the nucleus, where transcription occurs. Pregenomic RNA encapsidation occurs in the cytoplasm. Reverse transcription leads to negative-strand and then positive-strand synthesis. The nucleocapsid undergoes assembly with hepatitis B surface antigen, followed by budding and secretion in blood endoplasmic reticulum. (See companion Expert Consult website for color version.) (From Benhenda S, Cougot D, Buendia MA, Neuveut C: Hepatitis B virus X protein: molecular functions and its role in virus life cycle. *Adv Cancer Res* 2009;**103**:75-109.)

accomplished, followed by plus-strand synthesis and circularization of the genome. The progeny cores then bud into intracellular membranes and acquire glycoprotein envelopes to form nucleocapsids. Nucleocapsids are exported from the hepatocyte cytoplasm toward the cell membrane, where they become invested with surface proteins bound in the membrane bilayer, resulting in budding of mature virions into the bloodstream.

Although HBV can infect numerous tissues, including spleen, kidney, peripheral blood mononuclear cells, and pancreas, the virus replicates exclusively in the liver, because the tissue-specific viral promoter and enhancer are in liver cells. There is no in vitro HBV infection system that can support the entire life cycle of HBV. In the cell culture systems presently available, such as primary duck hepatocytes infected with DHV and immortalized human hepatoma cell lines such as HepG2 and HuH7, the viral replicative cycle is not cytopathic. The infected hepatocytes are normal morphologically and display growth rates identical to those of uninfected controls.[15,174] Human primary hepatocyte cultures are only susceptible to HBV infection for a limited time after explantation,[67] so usefulness has been limited.

Viral Binding and Cell Entry

Studies of the early phases of the viral life cycle have primarily used DHV. The binding reaction has two components: one is of low affinity and is nonsaturable, and the second is of high affinity and saturable.[110] At 37° C, cell entry and viral infection occur. After binding, the virus must fuse with the host cell membrane. This phenomenon appears to occur by a pH-independent mechanism. The binding and entry processes are slow, with maximal infection occurring after 16 hours of cell exposure to the inoculum.[161] The pre-S proteins appear to be involved primarily in the cell fusion interactions, because monoclonal antibodies to these proteins prevent infection.[110] The pre-S proteins also appear to control the narrow spectrum of host determination (i.e., if the virus entry process is bypassed by transfection into heterologous cells, heron HBV is able to replicate in duck cells, which normally are not susceptible to this virus).

The cellular receptors for human HBV are unknown and remain difficult to detect owing to the challenge of maintaining an HBV-susceptible cell line. The hepatotropism of HBV is presumed to be due to the presence of a specific receptor, although none has been identified.[182] Many proteins, such as apolipoprotein H[27] and endonexin 2 (a phospholipid-binding protein), bind to the HBV envelope glycoproteins, particularly S protein.[84] Receptors for pre-S proteins still have not been identified, and the biologic significance of these findings is yet to be determined. The mechanisms by which viral DNA is transported through the hepatocyte is not well understood but likely involve alteration of the nucleocapsid core protein after viral entry.[110]

In the nucleus, viral DNA is transformed to the cccDNA, a process that entails repair of the single-stranded gap, removal of the 5′-terminal structures, and covalent ligation of the strands.[2] Host mechanisms appear to contribute greatly to this process.[113]

Genomic Replication

The first step in HBV genomic replication is the encapsidation of the genomic RNA template.[201] The pregenomic RNA is encapsidated into the core particle.[59] Both C protein and *P* gene products are required to package this small RNA portion into the capsid.[85] Encapsidation of polymerase occurs by binding of the P protein to the RNA that will be packaged.[9] Single-stranded pregenomic

RNA is converted to partially duplex virion DNA through reverse transcription and elongations of the plus and minus strands.

Viral Assembly and Release

The 20-nm subviral particles are assembled between the endoplasmic reticulum and the Golgi apparatus.[92] These 20-nm particles contain predominantly S proteins, which are synthesized in the endoplasmic reticulum.[76] In addition, these particles may contain M subunits but generally do not have L proteins.[81] The assembly process is encoded totally in the S domain.[122] Assembled particles are transported through the secretory pathway and traverse the Golgi complex.[107,198] The S protein carries out the entire assembly process without the involvement of other viral proteins.[2] Therefore, subviral particles containing only envelope proteins are released. In vitro studies have shown that overexpression of L proteins gives rise to filamentous viral particles in the endoplasmic reticulum.[43] The overabundance of L, M, and S aggregates apparently is cytopathic to hepatocytes in vitro. Similar cytopathic features have been seen in human infections with HBV, yet the role of envelope protein expression in hepatocyte injury remains to be determined.[2]

The assembly of the Dane particle differs from the assembly of the 20-nm particles in that all three proteins, L, M, and S, are present.[81] Studies of HepG2 cell lines transfected with HBV mutants have shown that no virus budding occurs if the envelope proteins are not present (mutations in *S*) and that for virion formation and release, both L and S proteins are needed.[25] M proteins apparently are not necessary for viral assembly.

Viral Persistence

Nuclear cccDNA appears to be crucial to viral persistence. Hepatocytes that harbor this form of viral genome are the only ones that produce virus.[2] As mentioned earlier, the replicative cycle of HBV is not cytopathic to hepatocytes, and, therefore, infected cells multiply normally. The cytoplasmic mechanism of reverse transcription, which produces the cccDNA and consequently delivers this product to the nucleus, must therefore be passed on to progeny cells. When HBV DNA is integrated into the cell chromosome, viral DNA may be rearranged, although whether this happens before or after integration is unclear. This rearrangement may lead to disruption of viral genes, especially the core and polymerase genes, whereas the coding regions and promoters for the envelope proteins remain intact.[171]

IMMUNOPATHOGENESIS

HBV is not directly cytopathic, and the variability in liver damage is due to host immune responses. Although HBV preferentially infects hepatocytes and replicates therein, it can infect other liver cells, such as cholangiocytes, as well as cells in extrahepatic tissue such as peripheral blood lymphocytes, pancreatic acinar cells, cornea, spleen, thyroid gland, kidney, adrenal gland, and smooth muscle.[143]

Responses to HBV infection and the likelihood of developing chronic infection are dependent on both age at the time of acquisition and immune competence. Ninety percent of infants born to mothers who are HBeAg positive become chronically infected with HBV, compared with only 5 percent of those infected as adults. The production of antibodies to pre-S and S antigens by B cells, as well as cytotoxic T-lymphocyte (CTL) responses, mediates recovery from acute HBV infection. Individuals who clear HBV have a strong polyclonal human leukocyte antigen (HLA) class I–restricted CTL response to multiple epitopes in the HBV envelope, nucleocapsid, and polymerase regions. This CTL response can be reactivated many years after clearance of all detectable evidence of HBV infection.[131]

Infants infected perinatally are at the highest risk for development of chronic HBV infection. During childhood, those infected as neonates characteristically have high circulating levels of HBV DNA but low disease activity, with very low rates of HBeAg seroconversion, either spontaneously or after treatment with IFN.[131] Researchers have offered numerous hypotheses as to why immune tolerance develops in neonates. One theory proposes that transplacental passage of HBeAg induces $CD4^+$ anergy and, therefore, no CTL responses to HBeAg develop. However, HBeAg-specific T-cell proliferation eventually is detected in those who subsequently seroconvert, rendering clonal deletion an unlikely mechanism.[131] Defective interleukin-2 production has been demonstrated in children who have chronic HBV, although whether it is a cause or consequence of chronic infection is not clear.[75]

The development of chronic infection is either a failure of host immune responses or a testament to the ability of HBV to evade that response. As the virus replicates within hepatocytes, viral antigens appear on the cell surface. Subsequently, cytotoxic T lymphocytes directed against HBcAg infiltrate the liver and cause hepatocyte necrosis.[51] In addition, HBV interferes with the production of cytokines of the Th1 response, especially IFNs that would otherwise elicit class II major histocompatibility complex (MHC) antigen expression and enhance viral clearance. For reasons not fully understood, both the HBV-specific CTL response and the $CD4^+$ helper T-cell response are weak in chronic HBV infection. The high HBV viral load may lead to depletion of peripheral T-cell responses.[63] However, HBeAg, produced in large amounts in chronic HBV infection, and HBsAg share T-cell epitopes. HBeAg may enter the thymus and induce immune tolerance to both HBsAg and HBeAg by decreasing the production of HBV-specific cytotoxic T lymphocytes. However, these cells can be reactivated in patients who undergo a spontaneous or IFN-induced HBeAg seroconversion.[166] Soluble HBeAg may itself contribute to persistence of HBV; there is some evidence that HBeAg favors production of T-helper cell type 2 cytokines rather than T-helper cell type 1 cytokines, which have a greater role in noncytolytic control of HBV.[63] Persistence of HBV infection may also be due to infection of extrahepatic tissues such as the kidney.[63]

Fulminant hepatitis is seen in less than 1 percent of infected individuals and has a high mortality rate. It is characterized by a brisk immune response and viral clearance. Those who survive clear HBV and do not develop chronic HBV infection. A higher incidence of fulminant hepatitis occurs in those patients infected with HBV mutants that do not produce the HBeAg, suggesting either an increased rate of replication or lack of immune detection of the mutant HBV.[116]

Carcinogenesis

Hepatocellular carcinoma is a recognized sequela of chronic infection with HBV; worldwide, most cases of HCC are linked to HBV infection. In Taiwan, the incidence of HCC in chronically infected individuals is 200 to 812 cases per 100,000 person-years, compared with 10 to 30 cases per 100,000 person-years in the general population. In those with liver cirrhosis secondary to chronic HBV infection, the incidence increases to 1,000 to 5,000 cases per 100,000 person-years (1% to 5% per year).[40] Prior to effective therapies, the lifetime risk for development of HCC in a chronically infected person was estimated at 40 to 50 percent.[12] The incidence of HCC is associated with serum HBV DNA levels in a dose-response relationship.[38] The risk for HCC after treatment is not clear; most treated individuals remain HBsAg positive and remain at some risk. The age at which surveillance for HCC should commence and the optimal frequency has not been determined.[135]

The detection of integrated HBV sequences in both human HCC and animal models has led to numerous theories regarding the mechanisms leading to HCC. Current hypotheses center on the integration of viral DNA into host genome, which may be associated with activation of oncogenes, deactivation of tumor suppressor genes, or other genetic instability. The finding that HCC cells in an infected individual contain HBV DNA in discrete rather than random sites, indicating clonal expansion of tumor cells, supports this theory. In general terms, the integrated HBV may affect genes locally by replacing or activating genes by insertional mutagenesis, or HBV may affect more distant genes by means of gene products that can be diffused.[162] Integration of HBV occurs at random sites on host hepatocyte chromosomes rather than at one fixed site. HCC tissue can itself contain a variety of chromosomal abnormalities, such as polyploidy, allelic imbalance, and translocations.[158] More than a dozen genes have been implicated in HCC, not only suggesting heterogeneity of genetic etiologic factors but also indicating that an accumulation of genetic mutations is required for HCC to develop.

Although many mutations are found in HCC, they can be clustered into three main pathways.[202] The first is that of tumor suppressor or DNA damage repair genes typified by *TP53*. A mutation in *TP53* is detected in approximately 30 percent of HCC, although this figure varies by geographic region, being more common in China and less in Europe. The rate of *TP53* mutation is increased by exposure to aflatoxin.[158] A second pathway is that of cell cycle control, the *RB1* pathway. An example is the retinoblastoma gene, which is mutated in about 15 percent of HCC.[227] The final pathway associated with transformation of a normal hepatocyte to a malignant one is the β-catenin and adenomatosis polyposis coli *(APC)* gene system, which is involved in signal transduction. The E-adherin gene, which produces a protein that forms complexes with β-catenin, frequently is mutated in HCC.[186]

Abnormalities in hepatocyte regulatory genes may be activated by the integration of HBV X protein (HBx). HBx can function as a transcription activator, protease inhibitor, and effector of cell signaling pathways. Two other HBV proteins, middle hepatitis B virus surface protein and the large hepatitis B virus protein, have similar properties.[162]

The frequency and significance of integration of viral DNA into the host genome are unresolved issues in childhood HBV infection; some studies have shown early integration, whereas others describe it as a rare event.* Although HCC is detected most often after at least 20 years of chronic HBV infection, cases in children as young as 8 months old have been reported.[72,205,220] Childhood HCC associated with HBV infection has been described in both Asian[37,205] and Western[72,160] populations. Because most cases are reported retrospectively, data regarding incidence are not available. No guidelines have been developed for prospective monitoring of children with chronic HBV infection for development of HCC, although periodic measurement of serum α-fetoprotein levels and hepatic ultrasound evaluations are recommended in adults.

Genotype of HBV may be an indirect marker of HCC risk. Genotype C with TCC at codon 15 of the precore region is associated with an increased risk for HCC in a Hong Kong population with cirrhosis.[30] Prevention of HBV infection and eradication of existing infection remain the most effective measures to prevent HCC. After a nationwide hepatitis B vaccination program implemented in Taiwan in 1984, the incidence of HCC in children between 6 and 14 years old declined from 0.7 per 100,000 children between 1981 and 1986 to 0.36 per 100,000 children between 1990 and 1994.[35] The incidence of HCC was lower in vaccinated versus unvaccinated Taiwanese children, with an age- and sex-adjusted relative risk reduction of 0.31.[33] The 5-year survival rate in children with HCC is less than 30 percent, despite treatment.[223]

EPIDEMIOLOGY

HBV infection occurs throughout the world, although there are marked geographic differences.

Areas of high, intermediate, and low endemicity, as reflected by the number of carriers, have been identified. Highly endemic areas are those in which more than 8 percent of the population is infected. Examples include Southeast Asia, Africa, Commonwealth of Independent States, and China. More than 70 percent of the world's population lives in these high-endemicity areas. The Middle East, Central and South America, and parts of Eastern Europe are examples of intermediate-endemicity regions, where infection is found in 2 to 7 percent of the

*References 10, 36, 74, 181, 217, 221.

population. The United States, Australia, and Western Europe are areas of low endemicity, with chronic infection rates of less than 2 percent of the total population.[211] In areas of low endemicity, acute infections occur more commonly in adults, which, although causing significant morbidity, are less likely to result in chronic carriage than are asymptomatic infections in children.

In the United States, the prevalence of chronic HBV infection (HBsAg positive) among the general population, from 1999 to 2006, was 0.27 percent. This study revealed that 4.7 percent of the U.S. population had evidence of either past or chronic infection with HBV,[215] not statistically different from that reported in the National Health and Nutrition Examination Surveys (NHANES III) survey from 1988 to 1994.[147] The rates among ethnic groups varied, with non-Hispanic blacks having the highest rates (12.2%) compared with non-Hispanic whites (2.8%) and Mexican Americans (2.9%). The prevalence rate of chronic HBV infection was higher among foreign-born children (0.89%) than U.S.-born children (0.16%).[215]

HBV may be transmitted vertically, horizontally, parenterally, or sexually. Vertical transmission of HBV occurs in the perinatal setting when an infected mother transmits the infection to her child. Horizontal transmission occurs among children in groups with moderate to high endemicity[58] who were not infected at birth. This form of transmission occurs in households of an infected family member, in which other members acquire HBV without sexual or overt contact with contaminated bodily fluid. In adolescents and adults, infection is transmitted by contaminated blood or other bodily fluids through percutaneous or mucous membrane routes. Examples are intravenous drug use; occupational exposure to blood; sexual contact, especially in men who have sex with men; and nosocomial infections from contaminated shared equipment.[142]

In countries where HBV infection is highly endemic, perinatal or vertical transmission is very common, whereas in regions of low endemicity, sexual transmission is more common. If a mother is seropositive for both HBeAg and HBsAg, the risk for transmission of HBV to her child is 85 to 90 percent without immunoprophylaxis.[8] The most common risk factors for acquisition of acute HBV in adults in the United States from 1982 to 1998 were heterosexual exposure to a person with hepatitis or having multiple sexual partners (27%), intravenous drug use (18%), men who have sex with men (13%), household contact (3.6%), and occupational exposure (16%).[73] Approximately one third of people reported no risk factors during the study period.[73]

Within the United States, the number of reported cases of acute hepatitis B decreased 81 percent between 1990 and 2006 to the lowest rate ever recorded (1.6 per 100,000 population).[214] The largest decline was in children younger than 15 years old. Hepatitis B elimination strategies such as screening of pregnant women, universal immunization of infants, and catch-up immunization of older children are credited with the reduced incidence in children. Strategies to eliminate hepatitis B are outlined in Table 156-1.

The experience from Taiwan, the first country to implement mass vaccination against HBV, is encouraging. Since 1986, all neonates have been vaccinated against HBV. Seroprevalence of HBsAg declined from 9.8 percent before this strategy to 0.6 percent 20 years later.[150] There was a significant decrease in the incidence of HCC, from 0.54 to 0.20 per 100,000 children, between 1986 and 2000. The proportion of infants and children with hepatitis B as a cause of fulminant hepatic failure in Taiwan decreased from 82 percent before mass vaccination to 57 percent.[39]

Researchers have estimated that only 45 percent of the expected 20,000 HBsAg-positive women giving birth in the United States between 1993 and 1996 were identified.[187] This low figure may be due to numerous factors; women likely to be infected often do not receive prenatal care,[185] or women may be tested but the information not conveyed to the place of birth or to the pediatrician caring for the child.[8] Attention to this aspect of care is extremely important because the reduction in rate of transmission from mother to child with use of hepatitis B immunoglobulin (HBIG) and hepatitis B vaccine is as high as 90 percent.[197] HBsAg can be found in the breast milk of HBV-infected mothers. However, in studies performed in Taiwan and England, breast feeding by HBsAg-seropositive mothers did not significantly increase the risk for neonatal acquisition of HBV infection.[159] A study of 230 babies in China demonstrated that breast-fed babies had similar response rates to HBV vaccination and failure rates to HBV immunoprophylaxis as bottle-fed babies.[213] Effective immunoprophylaxis should allow for safe breast feeding.

TABLE 156-1 Strategies to Eliminate Transmission of Hepatitis B Virus Infection in the United States

- Universal vaccination of infants beginning at birth
- Prevention of perinatal HBV infection through:
  - Routine screening of all pregnant women for hepatitis B surface antigen (HBsAg)
  - Immunoprophylaxis of infants born to HBsAg-positive women and infants born to women with unknown HBsAg status
- Routine vaccination of all previously unvaccinated children and adolescents
- Vaccination of previously unvaccinated adults at increased risk for infection

From Mast EE, Margolis HS, Fiore AE, et al. A comprehensive immunization strategy to eliminate transmission of hepatitis B infection in the United States: recommendations of the Advisory Committee on Immunization Practices (ACIP), part 1: immunization of infants, children, and adolescents. *MMWR Recomm Rep* 2005;**54**(RR-16):1-31.

NATURAL HISTORY

Acute HBV Infection

Acute hepatitis B infection is most common in young men older than 19 years and women older than 40 years,[54,73] but most do not develop chronic disease. The clinical and serologic findings in acute hepatitis B infection are shown in Figure 156-3. Children infected

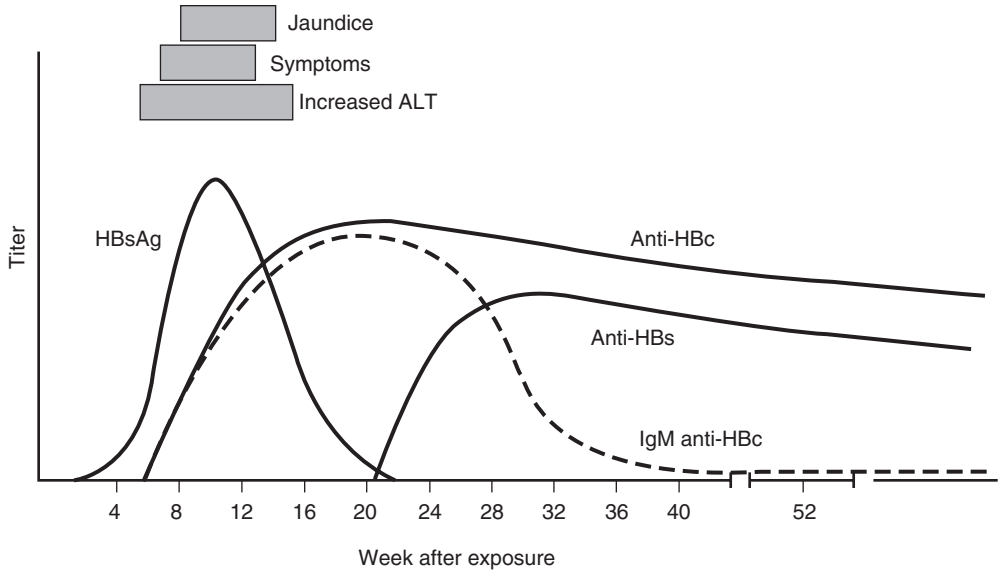

FIGURE 156-3 ■ Clinical and serologic features of acute infection with hepatitis B virus. Hepatitis B surface antigen (HBsAg) is detectable within 4 weeks and reaches a peak value at 12 weeks. This coincides with the onset of jaundice. Hepatitis B e antigen becomes detectable at the same time. Anti–hepatitis B core (Anti-HBc) IgM is detected from 6 to 8 weeks and peaks at 20 weeks. It then declines, but anti-HBc IgG persists. On resolution of acute infection, the serum contains anti-HBc, IgG type, and anti-HBs. ALT, alanine aminotransferase.

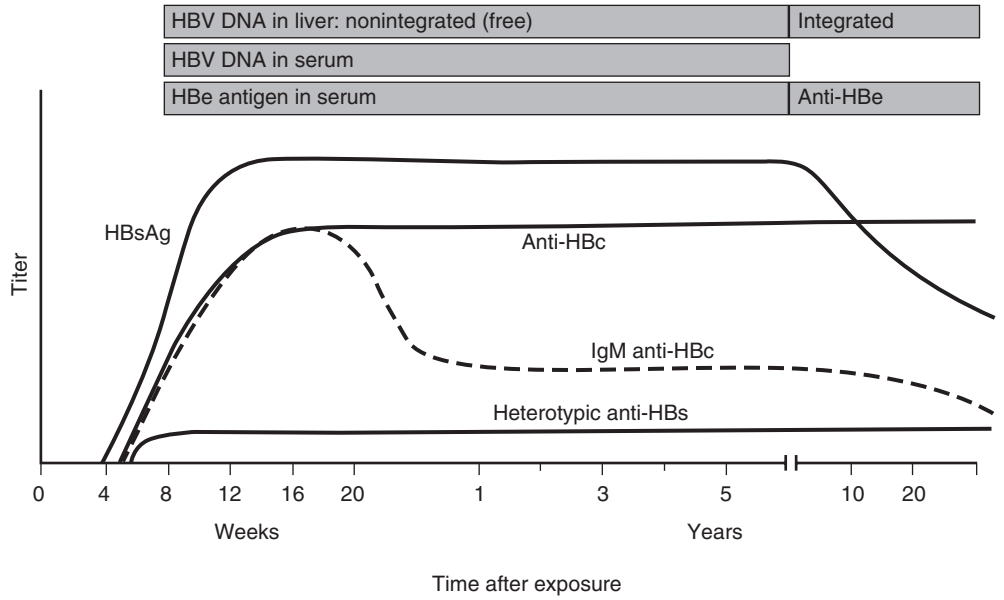

FIGURE 156-4 ■ Clinical and serologic features of chronic hepatitis B virus (HBV) infection. Hepatitis B surface antigen (HBsAg), hepatitis B e antigen (HBeAg), and anti–hepatitis B core (HBc) antibody are detectable and may persist for years. Seroconversion from HBeAg to HBe antibody is associated with very low levels of HBV DNA in serum. The diagnosis of chronic HBV infection is dependent on finding HBsAg for at least 6 months or the combination of HBsAg and anti-HBc of the IgG class.

perinatally rarely develop acute hepatitis, but fulminant hepatic failure can develop, particularly in infants born to HBeAg-negative mothers.[39]

Chronic HBV Infection

The natural history of chronic HBV infection in children has been examined in several populations. The clinical and serologic findings of chronic hepatitis B are shown in Figure 156-4. Most Chinese children, in whom chronic HBV usually is perinatally acquired, remain HBeAg positive, with very high levels of viral replication yet only minimal clinical liver disease.[133,134] In contrast, children in the West with chronic HBV infection frequently clear HBeAg and HBV DNA from serum during the first 2 decades.[22] In extended follow-up of 14.5 ± 6.1 years of 89

white children in Italy after seroclearance of HBeAg, 4 experienced reactivation, 3 of whom had HBeAg-negative hepatitis.[23] Those who lose HBeAg tend to have higher alanine aminotransferase (ALT) levels early in life, indicating more active liver disease. Some of the children (15.4%) become seronegative for HBsAg as well.[23] Reactivation of viral replication is observed only rarely. Children born to Asian and Afro-Caribbean mothers in the United Kingdom who acquired HBV infection perinatally had a much lower (29%) rate of HBeAg seroconversion than white children in this U.K. study (80%)[24] or Italian children (98%).[23] These differences are ascribed to the older age at acquisition of HBV in the Western children, associated with a more efficient immune response. These observations influence the management and counseling of children with chronic HBV infection as well as the design and interpretation of therapeutic trials.

The risk for acquiring chronic hepatitis B is related to a number of factors, such as very young age, other medical conditions, and other infections. If an infected person has other medical problems, such as end-stage renal disease requiring hemodialysis, or is coinfected with HIV, the risk for development of chronic HBV infection increases. The risk for development of HCC is increased in all HBV chronic carriers but especially those with active viral replication.[12] Four of 99 Italian children had HBeAg-positive cirrhosis at the start of the study, and after 14.5 ± 6.1 years follow-up 2 developed HCC and 2 had lost histopathologic features of cirrhosis.[21,23]

Extrahepatic manifestations of both acute and chronic HBV infection occur more commonly in adults. Up to 25 percent of adults with acute HBV infection have extrahepatic manifestations such as arthralgia and even serum-like sickness. Vasculitides can develop in both acute and chronic HBV infection, and examples include polyarteritis nodosa, renal disease, and mononeuritis.[146] Membranoproliferative glomerulonephritis is an extrahepatic manifestation of chronic HBV infection in some children.[109,194] There is a case report of epididymitis related to acute hepatitis B in a 12-year-old boy.[206]

HISTOPATHOLOGIC FEATURES

The purposes of obtaining a liver biopsy in chronic HBV infection are to quantify the severity of changes, to rule out other causes of liver disease, and to allow comparison of changes after treatment. In typical acute viral hepatitis, a liver biopsy usually is not required or indicated. If performed, the findings are liver cell degeneration and necrosis, with lobular disarray. The acute injury to hepatocytes is manifested as both ballooning and acidophilic degeneration, either of which can resolve or progress to cell death. Inflammatory cell infiltration and liver cell regeneration are also seen.[89]

The histopathologic changes of chronic HBV infection are characterized by portal tract inflammation, interface hepatitis, and fibrosis, which may progress to architectural distortion of lobules and eventual cirrhosis.[89] Chronic HBV infection is characterized by "ground-glass" cells (Fig. 156-5A), which are hepatocytes containing HBsAg and most easily identified by staining with orcein, Victoria blue, or aldehyde fuchsin. However, these cells also are found in other liver diseases, and the pattern of staining is important. In hepatitis B, ground-glass cells are found either singly or in clusters arranged in a haphazard pattern. "Sanded" liver nuclei are caused by accumulation of HBcAg and generally are identified by electron microscopy[94] or immunoperoxidase techniques (see Fig. 156-5B).

Histopathologic staging and grading systems are used to allow standardization and meaningful comparisons in chronic hepatitis. One such system is the Knodell-Ishak score, which evaluates four histopathologic features—each scored using specific criteria.[111] This system has proved reproducible, is now is in common use, and is also known as the modified histologic activity index (HAI). Other systems are the Batts-Ludwig[11] and METAVIR systems.[173] The systematic classifications are useful in estimating progression of disease and response to therapy and for comparing outcomes of therapeutic trials. A study from Poland demonstrated that these scores were useful

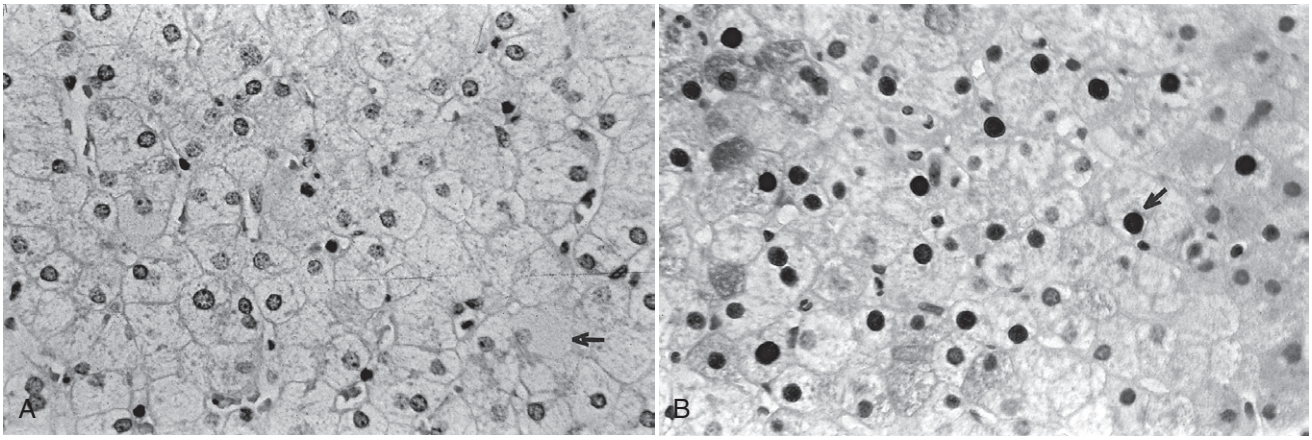

FIGURE 156-5 ■ A, Photomicrograph of a liver biopsy specimen from a child with chronic hepatitis B virus (HBV) infection. Ground-glass hepatocytes *(arrow)* are demonstrated (hematoxylin and eosin stain; original magnification ×20). **B,** Photomicrograph of the liver of a child with chronic HBV infection. The darkly stained nuclei *(arrow)* contain hepatitis B core antigen (HBcAg) (immunoperoxidase stain for HBcAg; original magnification ×20).

in comparing liver biopsy specimens in children before and after IFN-α treatment and that inflammatory but not fibrosis scores improved after treatment.[188] However, another study demonstrated interobserver variability in grading and staging of pediatric liver biopsy specimens.[218]

Serum markers of hepatic fibrosis, such as apolipoprotein A1, haptoglobin, and α2-macroglobulin have been investigated in children. They present many theoretical advantages for noninvasive monitoring of patients, but no single marker has yet proven useful in children with chronic HBV infection.[125] Serum noninvasive models using a combination of serum markers and enzyme immunoassays now more commonly used in chronic hepatitis C were applied to 179 adult patients with chronic hepatitis B.[164] The authors suggest that these values may be helpful in determining which patients with normal ALT values would benefit from early therapy.

Other noninvasive techniques studied in adults include transient elastography and acoustic radiation force impulse. These modalities appear promising in identifying patients with normal or near-normal ALT but significant fibrosis who might benefit from therapy.[108]

TREATMENT

Treatment of acute hepatitis B is purely supportive, and most patients recover fully and with permanent immunity (anti-HBs). The role of antiviral therapy in fulminant HBV infection has not been studied systematically. Treatment, when indicated, is directed at those with chronic HBV infection. In this setting, the long-term goals of therapy are eradication of HBV and improvement or regression of liver disease. Other goals for treatment include cessation or decrease in viral replication as indicated by loss of HBeAg and loss of HBV DNA from serum, clearance of HBsAg, normalization of liver histopathology, normalization of aminotransferase values, and reduction of the risk for HCC.

To date, no agents fulfill all of these goals in either adults or children. Children and adults have differences in immune tolerance and rate of progression of liver disease. Therefore, studies of treatments of chronic HBV in adults cannot be extrapolated directly to children. In addition, the timing and choice of therapeutic agent are crucial because of differences in age, maturity, stage in natural history, and comorbidities.

A child being considered for treatment should have serologic evidence of HBV infection, such as HBsAg for at least 6 months, as well as evidence of active HBV replication, HBeAg, or HBV DNA (in case of eAg-negative HBV infection). In addition, children with consistent elevation of ALT to at least twice the upper limit of normal are most likely to benefit from treatment. A liver biopsy should be obtained before the start of therapy to provide evidence of chronic hepatitis, to stage the disease, and to rule out other processes. In most studies performed before the high prevalence of eAg-negative infections, seroconversion from HBeAg to anti-HBe in serum was used as the primary outcome variable for response to therapy. Therapeutic trial results must be compared with the "background rate" of spontaneous conversion from HBeAg positive to anti-HBe, which in children younger than 3 years of age are very low (<2% per year) but increase with age so that in children older than 6 years of age, the yearly clearance rates vary from 14.3 to 35.3 percent.[34]

Quantitative HBsAg and quantitative HBeAg are being investigated as predictors for viral loads and treatment responses. Varying levels of quantitative HBsAg have been documented over the natural course of HBV infection and also between different genotypes.[96] Levels of HBsAg decrease with increasing age and progression of disease with increased fibrosis.[95] These values may be helpful in determining treatment strategies and algorithms for stopping therapy.[31,126]

Two medications that are approved in the United States for treatment of chronic HBV in young children younger than the age of 12 are IFN-α and lamivudine. Neither of these is still used in adults, because of the availability of drugs with better tolerance and better resistance profiles. Adefovir dipivoxil is licensed for adolescents age 12 years and older, and entecavir is licensed for those 16 years of age and older.

Interferon

IFNs are a family of cytokines with immunomodulatory, antiproliferative, and direct antiviral actions. There are three types: α, β, and γ. IFN-α has been the primary form used in treatment of chronic HBV infection. It induces the display of HLA class I molecules on hepatocyte membranes, which in turn promotes lysis by $CD8^+$ cytotoxic lymphocytes. At the same time, it directly inhibits viral protein synthesis.[127] IFN-α is available in several forms, including IFN-α2a, IFN-α2b, and lymphoblastoid IFN-α. Only IFN-α2a and IFN-α2b have been licensed in the United States for use in children. Peginterferon-α, in which the IFN molecule is attached to polyethylene glycol to allow for once weekly versus three times weekly injections, is the preferred form in adults but is not currently approved in the United States for children with chronic HBV.

IFN-α treatment led to loss of HBV DNA or HBeAg seroconversion in 20 to 58 percent of European as compared with 8 to 17 percent of control children.[210] Success rates were not as high for treatment of children in Asian countries, most of whom were perinatally infected; only 3 to 17 percent cleared HBV DNA or had HBeAg seroconversion in early studies.[118] However, in a large multinational, randomized control trial of IFN-α2b, no differences were found in loss of HBsAg between children born in Asian countries (22%) and those from Europe and North America (26%) if aminotransferase values were elevated.[190] If only children with elevated aminotransferase levels are selected for treatment with IFN-α, then children younger than 13 years of age with intermediate HBV DNA levels are most likely to have a good response, regardless of ethnicity.[190]

Reported studies of IFN-α included only children older than 18 months of age without hepatitis C and HIV coinfections because these factors may alter treatment algorithms. Children with evidence of active

immunologic responses to HBV (i.e., low levels of viral replication [HBV-DNA]) and high ALT values (greater than twice normal) are more likely to have a response to therapy with IFN-α.[208] Children who acquired disease by vertical transmission are more likely to have established immune tolerance and may be less likely to respond to treatment. Children with very low HBV DNA levels may be in the process of spontaneous seroconversion; therefore, an expectant policy may be prudent.

Ten percent of treated adults and children lose HBsAg, compared with 1 percent of untreated patients.[115,191] Long-term (1.1 to 11.5 years) follow-up of adult responders to IFN-α showed a significantly reduced incidence of HCC compared with either treated nonresponders or untreated control patients.[129] The long-term outlook for treated children is not yet clear. In a Turkish study, none of 23 treatment nonresponder developed cirrhosis or HCC at a mean follow-up of 4.5 years.[112] A second study compared long-term (5.6 ± 3.1 years) outcome in two groups of 37 children: one group was treated with IFN-α2β and the second control group of children age matched for age, sex, and baseline ALT level received no treatment. At time of follow-up, the rates of HBeAg and HBsAg loss were 54.1 percent (20/37) and 8.1 percent (3/37) in treated children compared with 35.1 percent (13/37) and 2.7 percent (1/37), respectively, in untreated children (NS). Children with ALT levels elevated more than twice normal who were treated had higher rates of HBeAg seroconversion at follow-up compared with children with elevated ALT who were not treated.[212] A study from Sweden demonstrated that pretreatment HBV DNA levels were associated with sustained virologic response.[189] Histologic outcomes in children with chronic HBV treated with IFN-α for 20 weeks have been reported in 93 children, average age 7.1 years, in Poland. Liver biopsy samples were obtained before treatment and 12 months after the end of the treatment and graded for fibrosis and inflammation using three different scoring systems. Thirty-five children underwent HBeAg/anti-HBe seroconversion. Liver fibrosis did not improve regardless of responder status, but inflammatory activity was decreased after treatment in both responders and nonresponders.[218]

Side effects of IFN-α include a transient influenza-like syndrome (fever, myalgia, headache, arthralgia, and anorexia) that occurs in virtually all patients at the start of therapy. Bone marrow suppression, especially neutropenia, is a common side effect, seen in 39 percent of children in one series.[93] Changes in personality, irritability, and temper tantrums are reported more frequently in children than in adults.[93,191] These problems resolve once treatment is withdrawn. Febrile seizures and marked elevation of aminotransferase levels have also been reported. Quality of life is impaired in children during IFN therapy compared with their pretreatment levels because of medication side effects and fear of injections. However, within 3 months of cessation of treatment, these effects are reversed.[93] Two meta-analyses of treatment of chronic HBV in children with IFN-α have been conducted.[208,209] Each concludes that treatment leads to a higher rate of HBeAg seroconversion than would occur spontaneously. Approximately two thirds of children treated with IFN-α show no sustained response to therapy; more effective and better- tolerated treatments are required.

HBV Polymerase Inhibitors

This class of agents includes the nucleoside and nucleotide analogs that inhibit HBV polymerase by incorporation into viral DNA, leading to termination. They are administered orally and generally well tolerated.[137]

Lamivudine

Lamivudine (2′,3′-dideoxycytosine), also known as 3TC, is an oral nucleoside analog. It is triphosphorylated intracellularly to an active intermediate that is incorporated into the growing DNA chain, thereby terminating the chain and inhibiting viral replication. Two large, randomized, controlled studies of lamivudine as initial treatment for chronic HBV infection in adults, showed serologic, biochemical, and histologic evidence of benefit.[55,117]

There are a number of studies demonstrating benefit of lamivudine in children. The first was a double-blind, placebo-controlled, randomized, multicenter study of lamivudine for 52 weeks in 191 children aged 2 to 17 years at a dose of 3 mg/kg/day (maximum dose, 100 mg) compared with placebo in 97 children.[101] All children in the study were HBeAg positive and had detectable HBV DNA and elevated ALT values. Twenty-three percent (44/191) of those treated with lamivudine cleared HBV DNA and HBeAg compared with 13 percent (12/97) in the placebo group (p <.05). Nineteen percent (31/166) developed the primary mutation associated with lamivudine resistance (i.e., tyrosine-methionine-aspartate-aspartate [YMDD]) in the first 48 weeks of therapy. Higher response rates were observed in those with higher ALT levels, as had been noted with IFN. In an open-label study of lamivudine in 29 adolescents and young adults with maternally transmitted chronic HBV infection in Taiwan, only those with ALT more than five times the upper limit of normal demonstrated a response (undetectable HBV DNA, normal ALT, and HBeAg/anti-HBe seroconversion) than control patients after 52 weeks of treatment.[151]

The optimum duration of lamivudine therapy was investigated in a multicenter, open-label study of prolonged therapy in children who had participated in the previous 1-year study.[192] Two hundred and 13 children were HBeAg positive; 133 had originally received lamivudine and 77 placebo, and all were offered lamivudine for a further 2 years. At the end of the study, 51 more children had achieved virologic response. However, 100/173 had developed the YMDD variant of HBV. The virologic response to those with YMDD variant was only 5 percent (5/100) compared with 49 percent (34/70) in those with wild-type HBV. Sixty-three children who were HBeAg negative (49 previously treated with lamivudine and 14 with placebo) at the start of the study were observed for 2 more years. At the end of the study period, 48/54 (89%) had a durable virologic response. No serious side effects of lamivudine were reported.

Based on the observation that both therapeutic response and development of resistant mutants increase in frequency with treatment duration, the optimal duration of lamivudine therapy has not been defined. In fact, this agent has largely been replaced in adult HBV treatment by newer drugs with more favorable resistance profiles.

Selecting the children most likely to benefit from lamivudine remains a challenge. Those most likely to have a sustained virologic response to lamivudine are those with HBeAg-positive chronic hepatitis and aminotransferase levels twice the upper limit of normal. If the YMDD variant emerges, lamivudine should be discontinued and liver enzyme levels monitored. In patients with advanced liver disease, alternate therapy may need to be provided. Lamivudine is excreted by the kidneys; thus, the dose should be reduced in patients with renal failure.

On cessation of therapy in adults, 25 percent of treated patients had elevation of serum ALT of up to three times baseline, as compared with 8 percent of placebo-treated patients. This "lamivudine withdrawal flare" may progress to jaundice and incipient liver failure, as noted in 2 of 41 patients in a Dutch study.[86] Therefore, monitoring patients after a course of lamivudine is important.

Combination of IFN-α and Lamivudine

Studies of combination therapy with IFN-α and lamivudine have been done in both children and adults. In adults with HBeAg-positive chronic HBV, peginterferon-α2a either alone or in combination with lamivudine for 48 weeks was superior to lamivudine alone.[121] At the end of week 72, the endpoint defined as HBeAg seroconversion, normalization of ALT and HBV DNA less than 100,000 copies/mL was achieved by 56 of 271 (21%) persons with peginterferon plus lamivudine compared with 62 of 271 (23%) persons who received peginterferon plus placebo and 28 of 272 (10%) who received lamivudine alone. An open-label, single-treatment arm, single-center study of combined IFN-α and lamivudine in children with perinatally acquired chronic hepatitis B was reported from the United Kingdom.[49] The treated children were traditionally regarded as poor responders, that is, infected in the first year of life, were HBeAg positive, and had normal aminotransferases. Only 23 children were treated with lamivudine alone for 8 weeks followed by lamivudine plus IFN-α 5 MU/m^2 three times weekly for 10 months. Five seroconverted to anti-HBe and four of these five became HBsAg negative and HBsAb positive. No child developed a YMDD mutant, and most (78%) became HBV DNA negative. These results have not yet been duplicated in larger studies.

Adefovir Dipivoxil

Adefovir dipivoxil is a synthetic nucleotide analog of adenosine monophosphate.[226] It suppresses HBV in both HBeAg-positive and HBeAg-negative adults and children, and drug resistance is less frequent and emerges later compared with lamivudine. Adefovir dipivoxil has been used to decrease HBV DNA and aminotransferase levels with prolonged treatment (144 weeks) in adults with HBeAg-negative chronic hepatitis B infection.[79] When treatment was withdrawn in one subgroup after 48 weeks, the virologic and biochemical benefits were lost, suggesting long-term treatment is required for viral suppression in those with HBeAg-negative chronic hepatitis B. The rate of development of resistance was somewhat lower (5.9% after 144 weeks) than that observed with lamivudine. Elevation of serum creatinine level was the most serious adverse event, and on-and-off treatment ALT elevations were common. In a double-blind randomized trial of 480 HBeAg-positive adults in China, suppression of HBV DNA was observed in those receiving adefovir 10 mg daily for 52 weeks whether they had wild-type or YMDD mutant infection.[226] A study of adefovir dipivoxil in 173 children with HBeAg-positive chronic hepatitis B showed that 23 percent of children aged 12 to 18 years of age were able to achieve a normal ALT and HBV DNA less than 1000 copies/mL compared with no subjects treated with placebo. No subjects developed mutations from the adefovir.[99] No statistical difference in this primary outcome was seen in patients younger than 12 years of age, but some HBeAg seroconversions were noted in the younger group of treated children. A follow-up of longer-term treatment in these patients noted continued safety, and some cumulative virologic responses with prolonged therapy, but treatment was discontinued in subjects with virologic failure (persistence of HBV DNA >1000 copies/mL) to minimize resistance risk.[100]

Entecavir

Entecavir (ETV) is a cyclopentyl guanosine analog that inhibits HBV polymerase; it was approved in the United States for use in patients 16 years and older in 2005.[137] Entecavir for 48 weeks suppresses HBV DNA levels in both HBeAg-positive and HBeAg-negative adults at higher rates compared with lamivudine.[132] Entecavir is considered one of the first-line agents for patients with HBeAg-positive or HBeAg-negative chronic HBV infection given its low risk for resistance. Entecavir is able to suppress both lamivudine-resistant and adefovir-resistant viruses, although a higher dose of the medication is indicated in lamivudine-experienced patients, owing to some cross resistance. Entecavir resistance is rare, except in individuals who harbor lamivudine-resistant HBV. Most adverse events are mild, although there is a theoretical risk for hepatotoxicity with lactic acidosis. A phase III randomized, controlled trial with entecavir in subjects 2 to 16 years of age is underway.

Tenofovir disoproxil fumarate (TDF) is a nucleotide analog reverse-transcriptase inhibitor (NRTI) that was licensed in the United States for use in adults with HBV infection in 2008. It is also used in combination with other antiretroviral agents for the treatment of HIV infection in adults. A randomized, placebo-controlled trial using tenofovir in adolescents demonstrated potent antiviral effects with acceptable safety. One hundred six patients were enrolled to take either tenofovir 300 mg or placebo once daily for 72 weeks. Normalization of the ALT value occurred in 74 percent of patients taking tenofovir and 31 percent of patients taking placebo. Adverse events were not common in either group, but the bone mineral density increased less in the tenofovir group than the placebo group over the course of therapy group.[149]

Table 156-2 summarizes published trials to date in children with chronic HBV.

HEPATITIS B IN SPECIAL POPULATIONS

Hepatitis B and Human Immunodeficiency Virus Coinfection

The prevalence and course of HBV infection in adults who are coinfected with HIV has been examined in numerous studies. Of 181 HIV-infected adults in Greece, 71.8 percent of the men who have sex with men and 91.7 percent of intravenous drug users had evidence of HBV infection.[57] In a study from Australia conducted between 1985 and 1989, men with HIV infection were more likely to have chronic HBV infection than were HIV-negative men.[17] In Western Europe and the United States among HIV-infected persons, 6 to 14 percent have chronic hepatitis B, including 4 to 6 percent of heterosexuals, 9 to 17 percent of men who have sex with men, and 7 to 10 percent of injection drug users.[3] A recent study in Thailand found the prevalence of HBV coinfection in perinatally HIV-infected adolescents to be 3.3 percent.[6] No evidence has been found for direct interaction between HBV and HIV. HIV and HBV coinfected individuals have higher circulating levels of HBV DNA but not worse hepatic necroinflammation.[45] In patients with

HBeAg, hepatitis B e antigen; IFN, interferon; NS, not significant.

HBV and HIV coinfection there are higher rates of HBV persistence, HBV relapse (reemergence of HBsAg), and more severe and rapid progression of liver disease. Spontaneous HBeAg seroconversion rarely occurs in this group. Special considerations for treatment and immunization are discussed in the appropriate subsections.

Hepatitis B in Solid-Organ Transplant Recipients

Chronic HBV infection became a relative contraindication to liver transplantation after initial poor results. In the 1970s and 1980s, more than 80 percent of patients became reinfected quickly and 55 percent died within 60 days of surgery. Patients who had recurrence of HBV infection after liver transplantation developed a characteristic histologic lesion, termed *fibrosing cholestatic hepatitis*, which eventually led to loss of the allograft.[14] The term *de novo HBV infection* is defined as HBV infection occurring in HBsAg-negative liver recipients who become HBsAg positive after transplant. In a retrospective study of 71 HBsAg-negative Taiwanese children who received orthotopic liver transplantation, 15.3 percent of patients developed de novo HBV infection. In this study, higher HBsAb titers (>200 mIU/mL) were thought to be sufficient to possibly prevent de novo HBV infection in liver transplant patients.[199] The demonstration in the 1990s that HBIG is efficacious in decreasing infection of the allograft has allowed successful transplantation. The use of long-term HBIG decreases the risk for recurrence to 30 percent at 12 months and increases patient survival to greater than 90 percent at 12 months after transplantation.[177] Lamivudine has been added to HBIG after the transplant procedure. In a study from China of 69 patients with chronic HBV infection who received liver transplants and treatment to prevent reinfection, 10 died fewer than 3 months after transplant.[222] Of the remaining 59 patients, 8 were not included in follow-up because they did not receive treatment with HBIG and lamivudine, leaving 51 patients in the final analysis. The mean follow-up was 14.1 months, and 2 of 51 had recurrent disease; 1 died and the infection in the other resolved.[222] The allograft reinfection rate is even lower if the patient does not have active HBV replication at the time of transplantation, which is why lamivudine has been added in the pretransplant period. The cost of HBIG is a major factor, and duration of therapy appears to be lifelong to maintain protective HBs titer.

HBV infection is the fourth most common cause of acute liver failure in adults in the United States.[157] Rarely, however, does a child in the United States with HBV need a liver transplant for either acute or chronic liver failure.[195] Of 215 children who underwent transplantation between 1986 and 1992 at a major French center, only 4 had HBV-associated disease.[141]

The course of HBV infection in heart transplant recipients was examined in a French study in which 69 of 874 heart transplant patients were infected with HBV, most through nosocomial infection during endomyocardial biopsies. HBV infection had little impact on 5-year survival.[139] In a group of 120 lung transplant recipients in Israel, 11 patients with either chronic hepatitis B or receipt of an organ from an HBcAb-positive donor were given lamivudine prophylaxis. Only 1 patient developed resistance, which responded to treatment with adefovir. Two patients had reactivation of HBV infection with high aminotransferase levels and high HBV-DNA levels.[184] In a study from Taiwan, overall patient and allograft survival after kidney transplantation were not affected by HBV infection, despite increased hepatic morbidity.[91] Of the 113 patients who received kidney transplants between 1986 and 1998, 20 patients were HBsAg positive and 9 were positive for both HBsAg and HCV antibody. Of the 20 who were infected with HBV alone, 4 developed fulminant hepatic failure and died within 2 years of renal transplantation, 2 developed cirrhosis, and 2 others developed HCC.[91] Overall, however, the 5-year survival was not dissimilar in those infected with HBV and those not infected.

The child most likely to be treated successfully with today's agents is one who acquired HBV beyond infancy, has evidence of immune responsiveness to HBV, and has mild to moderate inflammatory changes on liver biopsy. The child ideally has no other medical problems, and child and family can comply with the regimen and monitoring. A perinatally infected infant may still respond to therapy, as long as there is evidence of immune activation, indicated primarily by ALT values consistently at least one and one-half times the upper limit of normal.[98]

Even if the child has some success with treatment but remains HBsAg positive, the child is still at risk for HCC or reactivation to HBeAg and HBV. Yearly follow-up of virologic status, determination of α-fetoprotein level, and ultrasonography are recommended by most experts, even though clear evidence to support this practice is lacking.

IMMUNOPROPHYLAXIS

A comprehensive strategy to prevent HBV infection, both acute hepatitis B and the sequelae of chronic HBV infection, must eliminate transmission that occurs during infancy and childhood as well as during adolescence and adulthood. It has been clearly demonstrated that HBV transmission cannot be prevented through vaccination strategies targeting only the groups considered at highest risk for developing infection. A comprehensive immunization strategy is currently recommended by the Centers for Disease Control and Prevention (CDC). There are a number of parts to this strategy, as detailed in Table 156-3.

Two types of products are available for prophylaxis against HBV infection. HBIG provides antibody to hepatitis B surface antigen, which gives temporary (3 to 6 months) protection by means of passive immunity; it is indicated only in certain postexposure settings. Hepatitis B vaccine evokes active immunity and is recommended for both preexposure and postexposure prophylaxis.

Hepatitis B Immunoglobulin

HBIG is prepared from plasma known to contain a high titer of anti-HBs. The human plasma from which HBIG is prepared is screened for antibodies to HIV and HCV, and the process used to prepare HBIG inactivates and

TABLE 156-3 **Prevention of Horizontal Transmission Within the Home and School**

Home
Hepatitis B virus immunization of all household members
Universal precautions for all blood and body fluids

Ban on sharing potentially contaminated items such as razors or toothbrushes
School
Hepatitis B virus universal immunization
Universal precautions for all blood and body fluids
Coverage of all abrasions with dressings
Full participation by child in normal school life

eliminates live viruses from the final product. HBIG is used in the postexposure prophylaxis of neonates of HBV-infected women and for susceptible individuals with sexual, needle-stick, or mucosal exposures. It is administered intramuscularly. The dose for infants with perinatal HBV exposure is 0.5 mL. The dose for adults is 0.06 mL/kg. Efficacy ranges from 70 to 95 percent.[8] HBIG in large doses is used after liver transplantation in HBV-infected patients to prevent infection of the allograft. HBIG is typically administered together with the HBV vaccine.

Hepatitis B Vaccine

Hepatitis B vaccines are available as single-antigen formulations or are combined with other vaccines. The two licensed single recombinant vaccines are produced by using *Saccharomyces cerevisiae* (common baker's yeast), into which a plasmid containing the gene for HBsAg has been inserted. Purified HBsAg is obtained by lysis of the yeast cells and separation of HBsAg by biochemical and biophysical techniques. Hepatitis B vaccines are packaged to contain 10 to 40 μg of HBsAg protein/mL after adsorption to aluminum hydroxide (0.5 mg/mL). Vaccines available in the United States are Recombivax HB and Engerix-B. Recombinant HBsAg is also used in the three combination vaccines available in the United States: Comvax, Pediarix, and Twinrix. The immunogenicity is similar for all preparations.

The recommended series of three intramuscular doses of hepatitis B vaccine induces a protective antibody response (anti-HBs) in more than 90 percent of healthy adults and in more than 95 percent of infants, children, and adolescents. Hepatitis B vaccine should be administered into the deltoid muscles of adults and children or the anterolateral thigh muscles of neonates and infants; the immunogenicity is substantially lower when injections are administered into the buttocks. When hepatitis B vaccine is administered to infants at the same time as other vaccines, separate sites in the anterolateral thigh may be used for the multiple injections.

The vaccination schedule used most often for adults and children has been three intramuscular injections, the second and third administered 1 and 6 months, respectively, after the first. Each of the two available vaccines has been evaluated to determine the age-specific dose at which an optimal antibody response is achieved.

Perinatal transmission of HBV can be prevented effectively if the HBsAg-positive mother is identified and if her infant receives appropriate immunoprophylaxis. Administration of HBIG and the first dose of hepatitis B vaccine within 12 hours of birth prevents 90 percent of perinatal infections.[102] Serologic testing of infants who receive immunoprophylaxis to prevent perinatal infection should be performed to identify the 5 percent of infants who become HBV carriers despite these measures. Testing for anti-HBs and HBsAg in children 12 to 15 months of age determines the success of vaccination and, in the case of failure, identifies HBV-infected infants or those who may require treatment or revaccination. The following are the current recommendations as to timing of immunizations for infants in the United States.[144]

1. *Infants born to HBsAg-negative mothers* should receive the first single antigen vaccine dose at birth or before hospital discharge. The plan thereafter depends on whether a single antigen or combination vaccine is used. For single antigen vaccine, the second dose should be administered at age 1 to 2 months and the third at age 6 to 18 months. If combination vaccines are used, the first dose should be of a single antigen vaccine at birth or before hospital discharge. The second dose should be at 2 months, the third at 4 months, and a fourth dose at either 6 months or 12 to 15 months depending on the combination of vaccines used. Testing for serologic response is not necessary and is not recommended.
2. *Infants born to HBsAg-positive mothers* should receive 0.5 mL of HBIG and the first dose of single-antigen hepatitis B vaccine within 12 hours of birth, administered intramuscularly at separate sites. The infant can then complete the immunization series with either single antigen or combination vaccine. If using single antigen vaccine, the infant should receive the second dose at 1 to 2 months and the third when the child is at least 164 days (6 months) of age. If using combination vaccine, the child should receive single antigen vaccine and HBIG at birth and then combination vaccine at 2, 4, and either 6 months or 12 to 15 months depending on the combination. Premature infants of HBV-infected women should receive vaccine in the same schedule, but those weighing less than 2000 g at birth have a decreased response to hepatitis B vaccination below 1 month of age. For such infants the dose given at birth should not be counted as the start of the vaccine series and three additional doses of vaccine (for a total of four doses) should be administered beginning when the infant reaches 1 month of age.[144] Testing for serologic response (HBsAg and anti-HBs) should be done when the child is 12 to 15 months of age. If anti-HBs response is inadequate (<10 mEq/L) and the child is HBsAg negative, he or she should be revaccinated. If the child's anti-HBs titers are greater than 10 mU/L and the child is HBsAg negative, that child is immune and not infected. If the child is HBsAg

positive at age 12 to 18 months, he or she should be considered as potentially chronically infected and followed appropriately.

3. *Infants born to mothers whose HBsAg status is unknown* should receive the first dose of vaccine within 12 hours of birth. Meanwhile, a maternal blood sample should be sent for HBsAg testing. If positive, HBIG should be given as soon as possible (not later than 1 week of age). The infant then should complete the routine vaccination schedule. If the infant is preterm and weighs less than 2000 g and the mother's HBsAg is not established within 12 hours of birth, the infant should receive HBIG and single-antigen hepatitis B vaccine and then complete four doses of hepatitis B vaccinations.

Others Who Should Receive Hepatitis B Vaccine

All nonimmunized children and young adults younger than 19 years of age should begin HBV vaccination at any health care provider visit. For older children and adolescents aged 11 to 15 years, the routine three-dose schedule may be used, but a two-dose schedule of vaccination also has been approved, using the Recombivax HB vaccine. The adult dose (1.0 mL/10 μg) is administered to the adolescent, and the second dose is given 4 to 6 months later. Short-term (2-year) follow-up in groups immunized by either schedule showed similar rates of anti-HBs decline. Of emphasis is that a lower dose of vaccine is used in the three-dose schedule; if the original dose is not known, the full three-dose schedule should be used.[29] Immunization also should be offered to high-risk groups, although universal childhood immunization has created an immune adult population for the most part, except immigrants, who comprise the largest reservoir of adult HBV infection in the United States.

In a three-dose schedule, increasing the interval between administrations of the first and second doses of hepatitis B vaccine has little effect on immunogenicity or final antibody titer. The third dose confers optimal protection, acting as a booster dose. Longer intervals between the last two doses (4 to 12 months) result in higher final titers of anti-HBs antibodies. Larger vaccine doses (40 μg) or an increased number of doses is required to induce protective antibody in many hemodialysis patients and other immunocompromised persons (e.g., those who take immunosuppressive drugs or who are infected with HIV). Children with end-stage renal disease respond better than do adults to HBV immunization. Ninety percent of pediatric chronic dialysis patients and 100 percent of children vaccinated before beginning hemodialysis became anti-HBs positive in one study.[65] An immunocompromised person who has previously shown an adequate anti-HBs antibody titer that then falls to less than 10 mIU/mL should receive a booster dose.

Testing for immunity (anti-HBs titer) is advised only for patients whose subsequent clinical management depends on knowledge of their immune status (e.g., infants born to HBsAg-positive mothers, hemodialysis patients and staff, patients with HIV infection). Postvaccination testing also should be considered for those at occupational risk who may have exposures from injuries with sharp instruments because knowledge of their antibody response helps determine appropriate postexposure prophylaxis.

When revaccinated, 15 to 25 percent of people who do not respond to the primary vaccine series produce an adequate antibody response after one additional dose and 30 to 50 percent do so after three additional doses.[97] Therefore, revaccination should be considered for people who do not respond to the initial series.

The duration of vaccine-induced immunity has been evaluated in long-term follow-up studies of both adults and children. The duration of response from neonatal or later immunization is still not clear, but studies in both Asian and European children vaccinated in infancy demonstrate immune memory persisted at least 10 years in Italy,[225] was 12 years in Hong Kong,[224] but started to wane by 15 years post immunization in Taiwanese children.[138] Booster doses were administered to the children in the latter study with anti-HBs titers less than 100 mIU/mL, and 4 of 128 demonstrated no response.[138] A previous study from the same group demonstrated excellent response in all subjects to a booster dose at age 10 years in those who were anti-HBs seronegative despite neonatal vaccination after being born to HBsAg- and HBeAg-positive mothers.[88] The timing and necessity of a booster dose is still unclear and is not recommended on a population basis.[103]

Therapeutic vaccination, that is, immunization of those already infected in an effort to boost their HBV-specific T-cell responses, has shown limited clinical success in adults. However, a trial of combination immunization (pre-S2/S vaccine) with IFN-α2b compared with IFN-α2b alone in children with chronic HBV infection did not show any benefit compared with IFN-α2b alone.[82]

Vaccine Side Effects and Adverse Reactions

Hepatitis B vaccines have been shown to be safe for both adults and children. Anaphylaxis is the only serious adverse event in children and adolescents; the observed risk was reported in 2003 as 1.1 per million vaccine doses administered.[18] Pain at the injection site (3% to 29%) and a temperature greater than 37.7° C (99.9° F) (1% to 6%) have been the side effects most frequently reported, but they were reported no more frequently among vaccinees than among subjects receiving a placebo.[28,204] In the United States, surveillance from the CDC of adverse reactions has shown a possible association between Guillain-Barré syndrome (GBS) and receipt of the first dose of plasma-derived hepatitis B vaccine in adults; plasma-derived HBV vaccine is no longer in use. An expert review did not accept or reject a causal association between HBV vaccine and Guillain-Barré syndrome.[28]

Reports of multiple sclerosis developing after vaccination for HBV led to concern that the vaccine might cause multiple sclerosis in previously healthy subjects. This theory was refuted in a nested control study of two large cohorts of nurses in the United States that compared the HBV immunization histories of each of 192 women who developed multiple sclerosis with five healthy controls. No association was found.[5] In a case crossover study using the European multiple sclerosis database, recent vaccination against HBV, tetanus, or influenza did not appear to increase the short-term risk for relapse in multiple sclerosis.[46]

Until 1999, hepatitis B vaccines were prepared with thimerosal (sodium ethylmercuric thiosalicylate) to prevent bacterial and fungal contamination. This preservative aroused public concern regarding mercury toxicity and the amount of mercury exposure relative to body weight. No adverse outcomes were associated clearly with thimerosal use, but HBV vaccination of neonates was suspended temporarily in 1999 until thimerosal-free vaccines became available, unless the mother was infected with HBV. Two thimerosal-free hepatitis B vaccines now are available in the United States for use in infants. Hence, parents can be reassured about the lack of exposure to mercury in hepatitis B vaccines.

Contraindications

There are only a few clinical situations in which hepatitis B vaccine is not recommended; those with a history of anaphylaxis to the vaccine and those with history of hypersensitivity to yeast. Vaccination should be deferred in those with an intercurrent moderate to severe illness. Pregnancy is not a contraindication to immunization.[144]

Recommendations to Prevent Household Transmission

When a person is found to have acute or chronic infection with HBV, immunization of household contacts is recommended. Guidance on universal precautions should be provided. As outlined in Table 156-4, parents of infected children and siblings should learn to treat bodily fluids, especially blood, as potentially infectious. All bloody emissions and blood-soiled items should be handled with gloves, and any blood-stained items should be either cleaned with bleach or disposed of carefully. Both the infected person and others in the house should cover skin abrasions with waterproof bandages. Razors and toothbrushes never should be shared. If needle sharps are in use, they should be secured and disposed of according to local guidelines. Schools, workplaces, and health care providers should practice universal precautions for all individuals regardless of whether HBV status is known.

TABLE 156-4 **Recommended Physician Visits for Children with Chronic Hepatitis B Virus Infections**

ALT, alanine aminotransferase; AST, aspartate aminotransferase; CBC, complete blood cell count; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen.

FUTURE STRATEGIES/TARGETS FOR TREATMENT

As new technologies are developed, potential treatments for HBV infection continue to emerge. These can be classified as (1) disruption of HBV life cycle other than HBV polymerase-based replication, (2) gene therapy, and (3) immunomodulators other than IFN-α.

Disruption of the formation of the nucleocapsid by members of the heteroaryl dihydropyrimidine class or phenylpropanamides have shown some efficacy in cell and mouse models.[137] Direct manipulation of the HBV gene offers the possibility of viral eradication using technology such as small interfering RNAs (siRNAs), once technical problems such as introduction of siRNAs into hepatocytes and prevention of enzymatic degradation have been overcome. However, proof of principle has already been demonstrated in mice. Short hairpin RNAs, a form of RNA interference, homologous to HBV RNAs were introduced into a cell culture model and into immunocompetent and immunodeficient mice. There were substantial reductions in mouse liver HBV RNAs and replicated genome as well as a reduction of 84.5 percent in secreted HBsAg in mouse serum.[145] siRNA molecules against different regions of the HBV gene have been shown to decrease HBsAg secretion in a human hepatoblastoma cell line.[114] Another group has shown that this effect can persist through multiple cell passages, suggesting integration of siRNA into the HBV genome.[167] Recently, altritol-containing synthetic siRNAs were tested in vivo in an HBV transgenic mouse model, and these were capable of silencing HBV replication without evidence of off-target toxicity.[80] Other members of the IFN class (e.g., IFN-γ, IFN-λ) as well as cytokines have shown some efficacy in either cell culture or animal models but have not yet been tried in humans.[137]

Despite advances in treatment, prevention of new infections must remain at the forefront of all therapeutic endeavors. Vertical transmission of HBV to children can be prevented by proper antenatal testing, careful follow-up of results, and availability of immunization programs to infants.

HEPATITIS D

Hepatitis D virus (HDV) is a subviral particle that requires a helper virus, HBV, to establish infection. As a subviral particle, HDV, which also is known as the delta agent or virus, does not encode its own envelope protein and requires HBV envelope production to become an infectious virion. HDV first was described in 1977 when a new antigen was described in the hepatocytes of patients infected with HBV. Transmission experiments

demonstrated that the antigen was indeed a new virus.[168] Infection with HDV and HBV can be contracted at the same time (coinfection), or HDV can be contracted as a new infection in a person previously infected with HBV (superinfection). There are currently eight major genotypes (clades) of HDV.[163,170] There is geographic variation in both incidence and genotype distribution.[183] HDV genotype I is the most frequent genotype found worldwide, but HDV genotypes 2 and 4 are found in the Far East and are associated with milder disease.[124] HDV genotype 1 infection appears to be associated with a more fulminant hepatitis in acute infection and increased rates of cirrhosis and HCC compared with genotype 2.[219]

VIROLOGY

HDV is a spherical particle with a diameter of 36 nm.[148] When the envelope is degraded, a nucleocapsid containing hepatitis D antigen (HDAg) and the HDV RNA genome is released. The two forms of HDAg are the small s-HDAg, which is 195 amino acids in length and is required for replication, and the larger l-HDAg, which is 214 amino acids long, is required for virion assembly, and inhibits HDV replication.[148] s-HDAg is a nuclear protein that undergoes phosphorylation by protein kinase C, and inhibitors of protein kinase C inhibit HDV replication in cell culture systems.[41] The ratio of the two forms of HDAg found in patients may vary.

The HDV RNA genome is single stranded and circular, with a length of 1679 nucleotides. During viral replication, the genomic RNA serves as a template for complementary RNA, which in turn is a template for more genomic RNA. A host-derived RNA polymerase is required.[207] Each copy of the genome and antigenome contains ribozyme activity that cleaves RNA and is required for HDV replication.[148] Posttranscriptional modification of the RNA leads to the production of the l-HDAg in addition to the s-HDAg already transcribed.[41,207]

To leave the host cell, HDV RNA and HDAg must be packaged into virions. The l-HDAg undergoes isoprenylation of a cysteine residue near its C terminus to allow virion assembly. Inhibition of this isoprenylation interferes with viral production by preventing interaction with HBsAg.[41] Once this interaction occurs, HBsAg and host cell membrane lipids enclose HDV RNA, l-HDAg, and s-HDAg to form virions. Noninfectious HDV particles, which contain only l-HDAg and HBsAg, can be found in serum.[148]

EPIDEMIOLOGY

The epidemiology of HDV infection parallels that of HBV infection, for obvious reasons. Modes of transmission of HDV also are similar to those for HBV and include direct or indirect parenteral exposure to blood or body fluids and sexual and perinatal transmission. Sexual transmission is less efficient than that of HBV, as evidenced by the relatively low frequency of HDV infection in homosexual men.[179] Perinatal transmission can occur but is rare because HBV carrier mothers also infected with HDV usually are anti-HBe positive and thus less infectious. Intrafamilial transmission of HDV has been demonstrated in endemic areas, such as southern Italy, by means of a combined epidemiologic and molecular study, which demonstrated that within family units the HDV strains were nearly identical.[152] Transmission of HDV infection has also been documented among residents of institutions for the developmentally disabled.

The geographic differences in HDV endemicity in the world are great, and four levels have been characterized. High endemicity (i.e., HDV is found in more than 20% of asymptomatic HBV carriers and more than 60% of HBV carriers with chronic liver disease) is seen in northern South America and Africa as well as in Romania.[35] In these populations, HDV superinfection of HBV carriers is a significant cause of chronic liver disease and causes outbreaks of fulminant hepatitis. In these areas, HDV infection is seen commonly in both children and adults and household transmission has been implicated. Parts of the Middle East, Africa, some Pacific Islands, and parts of Asia report intermediate HDV endemicity (in 10% to 20% of asymptomatic HBV carriers and 30% to 60% of HBV carriers with chronic liver disease). Infection in these regions occurs predominantly in adults, and outbreaks are uncommon, but HDV is an important cause of chronic liver disease. Low endemicity (in 3% to 9% of asymptomatic HBV carriers and 10% to 25% of HBV carriers with chronic liver disease) is observed in most developed countries, including the United States, but subpopulations in these countries, such as parenteral drug abusers and prostitutes, have a high infection rate. In areas of low HBV endemicity, transmission of HDV appears to be mainly by the percutaneous route, with higher rates of HDV infection found in intravenous drug users and hemophiliacs than in other HBV high-risk groups. HDV is considered only a moderately important cause of chronic liver disease in developed countries.[217] Finally, for as yet unexplained reasons, certain subpopulations have a high carriage rate of HBV but virtually no HDV infection; they include American Indians, Alaska Natives, and residents of some Asian countries.

Within the U.S. blood donor population, the prevalence of HDV infection is low; only 1.4 to 8 percent of donors are infected or have evidence of prior infection.[4] Estimates from the CDC for 1990 indicate that among the approximately 250,000 cases of acute HBV infection each year, 7500 simultaneously acquire HDV infection. There are about 70,000 carriers of HDV in the United States, where about 1000 deaths per year are caused by chronic HDV and 35 by fulminant HDV. In certain regions, the prevalence of HDV infection appears to be decreasing. In Italy, the prevalence of HDV infection in HBsAg carriers decreased from 23 percent in 1987 to 14 percent in 1992 and 8.3 percent in 1997.[66,175] Corresponding data for the United States are not available.

IMMUNOPATHOGENESIS

Unlike HBV, HDAg is found only in the liver or serum.[69] The mechanism by which HDV infection leads to hepatic injury has not been elucidated. Despite some evidence that HDV can be directly cytopathic, cytopathic viruses

seldom result in chronic infections. In addition, some HDV carriers have no evidence of hepatic cell damage. Both cellular and humoral components of the host immune system are involved in the response to HDV, although the relative contribution of each is controversial. Investigations into the humoral response to HDV demonstrated that HDAg contains epitopes or immunogenic domains to which sera from acutely infected humans and woodchucks react. The predominantly recognized epitopes are not exposed on the virion surface; thus, antibodies that recognize these epitopes cannot neutralize virus particles, which may explain why no association exists between the humoral response and clinical outcome.[148] Autoantibodies, especially liver-kidney microsomal type 3 antibodies and anti–basal cell layer antibody, are found occasionally in people with HDV infection. The significance of these antibodies is unclear, but they may play a role in the immunopathogenesis of HDV.

Cellular immune responses to HDV also have been demonstrated. Both $CD4^+$ and $CD8^+$ lymphocytes have been found in liver of patients infected with HDV; it is not clear whether these cells contribute to hepatitis or aid in control of HDV infection.[148] Patients with HDV superinfection of chronic HBV who had peripheral $CD4^+$ cells that reacted to four epitopes on HDAg were seronegative for HDV IgM, implying inactive disease.[152] Such $CD4^+$ T-cell clones produce IFN-γ and may be directly cytopathic. Individuals without these specific $CD4^+$ cells had active HDV disease.[155] These epitopes are in highly conserved regions of HDV, which is encouraging for the prospect of vaccine development.

An unusual mechanism of HDAg presentation by hepatocytes has been reported. The processing of HDAg peptide appears to occur outside the cell, where the peptide is cleaved into smaller fragments that bind to class II major histocompatibility complex molecules of all three human leukocyte antigen types found on hepatocytes and mononuclear cells. This form of antigen presentation could have many possible effects on T-cell responses: amplification of T-cell response to HDAg, stimulation of cytotoxic T cells to kill uninfected hepatocytes, or exhaustion of T-cell responses to HDAg, allowing infected cells to escape detection.[148]

The relationship of HBV infection status to pathogenesis of HDV is also unclear. Patients with active HBV replication (i.e., HBV DNA and HBeAg seropositive) have high levels of HDV viremia.[168,169] Conversely, in HBV and HDV carriers without liver disease or with minimal inflammatory hepatic lesions, markers of HBV replication are absent and HDV viremia is low.[19,169] In coinfected liver transplant recipients, HDV reinfection can occur without evidence of active HBV replication but necroinflammatory activity does not develop until HBV infection is reactivated.[50]

DIAGNOSIS

Establishing the diagnosis of either acute or chronic HBV infection is a prerequisite for the diagnosis of HDV infection, which is made by detection of antibody to HDV (anti-HDV). HDV antigen can be measured in serum, but it is usually present only transiently during acute infection and in immunosuppressed individuals.[124] Assays for both IgM and IgG anti-HDV are available. HDV RNA can be detected by reverse-transcriptase and real-time polymerase chain reaction assays, but these tests are not available commercially.

HDV infection may occur at the same time as HBV infection, a pattern that is termed *coinfection*. If an individual has acute, resolving hepatitis B, the HDV infection also will resolve.[52] In this instance, anti-HDV is found in the IgM form during the acute illness and persists for 2 to 6 weeks. Subsequently, IgG anti-HDV is found in serum, but it also diminishes to undetectable levels when the HBV infection resolves (Fig. 156-6). In HDV superinfection, both IgM and IgG anti-HDV are detected. Most often, superinfection with HDV leads to chronic HDV infection, diagnosed by persistence of both IgM and IgG anti-HDV (Fig. 156-7). Anti-HDV becomes predominantly IgG after about 6 weeks and persists if infection does not resolve; titers correlate well with ongoing viral replication.

Histopathologic features of HDV infection are very similar to those of isolated HBV infection (see earlier discussion). HDAg can be identified in nuclei and, to a lesser extent, in the cytoplasm of infected hepatocytes.

CLINICAL MANIFESTATIONS

In general, coinfection with HDV infection does not have clinical features that distinguish it from HBV infection alone. Symptoms develop 2 months after exposure, are similar to those of acute HBV infection, and usually resolve by 4 months after exposure. However, two peaks in aminotransferase levels often are noted, a pattern that is unusual in HBV infection alone. The infections resolve together.[53] Coinfection with both viruses does not increase the risk for development of chronic HBV infection.[136]

HDV superinfection in individuals with chronic HBV infection have different manifestations. HDV infection becomes persistent in most individuals (Fig. 156-8), and the predominant clinical pattern of chronic HDV infection varies by geographic location. In the United States and Europe, HDV superinfection leads to chronic liver disease in more than 90 percent of cases, whereas in some Pacific Island and African populations, most individuals with chronic HDV are asymptomatic.[169] When chronic liver disease does occur, the progression to cirrhosis is rapid; in studies in both adults and children, cirrhosis has been noted to occur in as few as 2 to 10 years. The cirrhosis associated with HDV infection has two patterns: in a minority of patients, especially the high-risk drug users, it progresses rapidly to hepatic failure and portal hypertension. In others, more stable cirrhosis occurs, with little inflammatory component, compatible with prolonged survival.[22] In a small minority of those who are superinfected, a self-limited hepatitis develops and subsequently both HBV and HDV infections are cleared. HDV infection has been demonstrated to lead to HCC at a younger age and a higher rate than does HBV

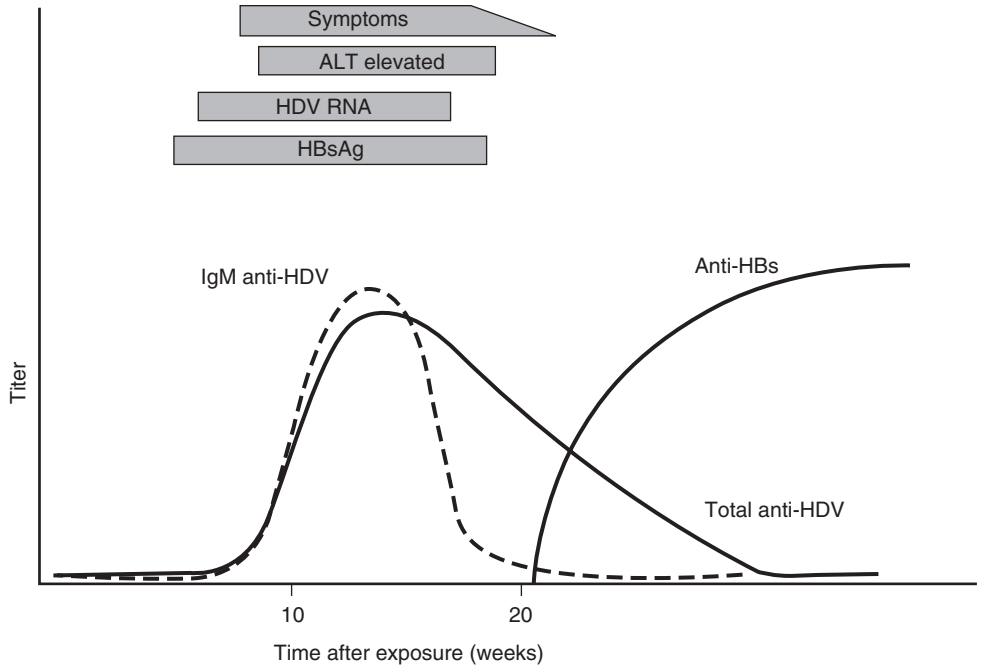

FIGURE 156-6 ■ Serologic events during hepatitis B virus (HBV) and hepatitis D virus (HDV) coinfection that resolves. After exposure to both viruses, hepatitis B surface antigen (HBsAg) and HDV RNA can be detected shortly before the onset of symptoms. Serum alanine aminotransferase (ALT) is elevated for the duration of detectable serum HDV RNA and HBsAg. Serum IgM anti-HDV level rises when symptoms are present and falls as HDV infection resolves and the anti-HBs titer becomes elevated. When both infections have resolved, anti-HBs is detectable in serum but total anti-HDV is very low.

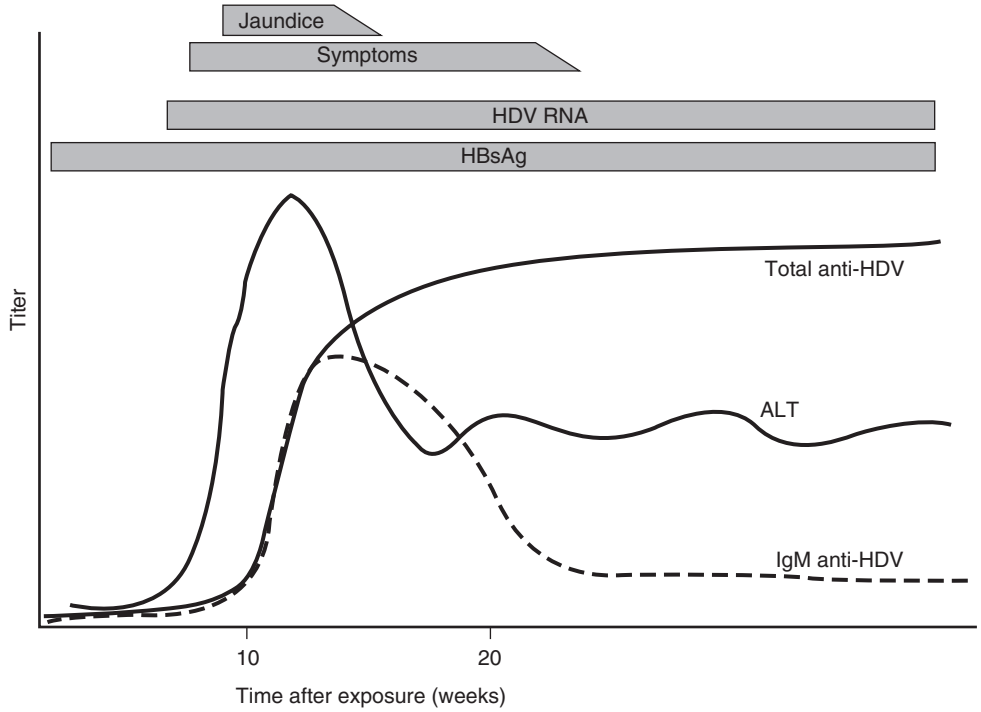

FIGURE 156-7 ■ Serologic events during hepatitis B virus (HBV) and hepatitis D virus (HDV) superinfection. If an individual already infected with HBV is infected with HDV, there is a marked elevation of alanine aminotransferase (ALT) coincident with the onset of symptoms and the onset of jaundice. HDV RNA also can be detected at the onset of symptoms. ALT levels fluctuate over the next few months as IgM anti-HDV decreases and total anti-HDV rises. Throughout the course of HDV superinfection, hepatitis B surface antigen (HBsAg) remains detectable.

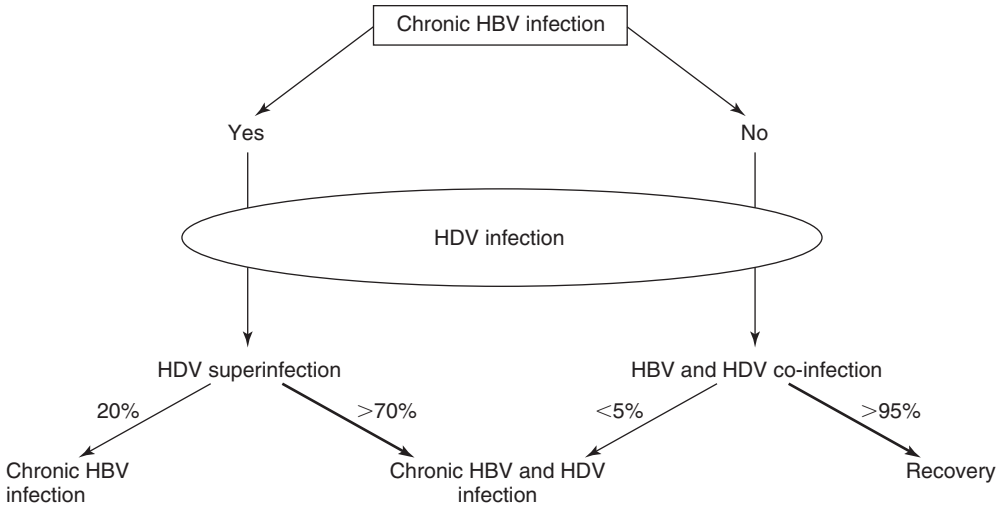

FIGURE 156-8 ■ Outcomes of hepatitis B virus (HBV) and hepatitis D virus (HDV) superinfection and coinfection. When a person already infected with HBV becomes infected with HDV there is a greater than 70 percent chance of becoming chronically infected with both HDV and HBV. In contrast, if a person acquires HBV and HDV infection de novo, there is less than a 5 percent chance of chronic HBV and HDV infection.

infection alone.[169] In a study of 166 patients with HBV and HDV from Romania, the median survival after the diagnosis of HDV-compensated cirrhosis was 58.3 months.[70] A multicenter European study of 200 HBsAg-positive patients with compensated cirrhosis found that 39 (20%) were anti-HDV positive. Those with HDV, HBV, and cirrhosis were younger than those with only HBV and cirrhosis; indeed, HDV infection may lead to the development of cirrhosis 15 years earlier.[62] In this study, HDV infection increased the risk for HCC three times and risk for mortality twofold compared with those with HBV and cirrhosis.[62] The natural history in those without cirrhosis is difficult to establish. In a study of 13 institutions for those with development disabilities in Illinois, 67 of 238 (28%) of HBsAg carriers also had anti-HDV antibodies.[83] Long-term (20 years) follow-up information was available on 65 of 66 anti-HDV– and HBsAg–positive individuals and 166 persons who were HBsAg positive. Liver-related deaths occurred in 7 of 65 (11%) anti-HDV–positive persons but only 1 in 166 anti-HDV–negative person.[1] Hepatitis D was associated with both a higher rate of chronic liver disease and a higher liver-related mortality rate.[1]

A retrospective study of 188 chronically HDV-infected individuals in Italy was performed over an 8-year period. At presentation 44 percent of patients had chronic hepatitis and 56 percent had cirrhosis. A fourth of the patients with chronic hepatitis progressed to cirrhosis during the study period. In 40 patients the viremia resolved either while on therapy or spontaneously. Nine percent of patients were diagnosed with HCC during the 8-year follow-up period.[154]

Children with HDV infection follow a course similar to that of adults. In one European series, the subset of children chronically infected with HBV who also were infected with HDV had more advanced liver disease and the prevalence of HDV infection increased in parallel with the activity of hepatitis. During the study period, disease progressed more rapidly in children infected with both viruses.[61] Testing for HDV infection is recommended in any child with chronic hepatitis B and unusually severe liver disease or an acute exacerbation of stable liver disease.

HDV infection after liver transplantation can appear without apparent HBV reinfection of either the graft or serum. However, use of PCR assay has demonstrated that low levels of HBV infection do, in fact, occur in patients with recurrent HDV infection, and this replication of HBV is sufficient to permit replication of HDV. The HDV virion found in such infections shares the characteristics of typical HDV infection.[20]

TREATMENT

Although several antiviral agents have been studied, the only treatment that has had any beneficial effect in HDV infection is IFN-α. Trials in adults, in both Europe and the United States, have shown that treatment with either 9 million units three times weekly or 5 million units daily of IFN-α results in normalization of serum aminotransferase levels, decrease or disappearance of HDV-RNA from serum, and improvement in hepatic inflammation in about 50 percent of cases.[61] However, most patients experienced a relapse shortly after treatment was discontinued. Response maintained after treatment was noted primarily in individuals who became HBsAg negative.

Pegylated INF-α2b has shown promise as a treatment for chronic HDV in two small trials. Fourteen patients were treated with pegylated IFN-α2b 1.5 μg/kg weekly for 12 months and 6 (43%) had a sustained virologic response (undetectable HDV RNA) 6 months after the end of treatment.[26] Combination ribavirin and pegylated IFN-α2b did not improve virologic response compared

with pegylated IFN-α2b alone.[153] No factors predictive of response have been identified. Prognosis in nonresponders to IFN-α and in those who relapse has been poor. The author of an editorial in *Hepatology* recommended continuation of IFN-α or pegylated IFN-α2b in patients with a decline in HDV RNA as long as possible, until HDV RNA and HBsAg disappear.[60] A recent randomized trial compared a 48-week treatment regimen of pegylated IFN-α2a plus adefovir dipivoxil, pegylated IFN-α2a alone, and adefovir dipivoxil alone. Twenty-three percent of patients treated with combination therapy and 24 percent of those treated with pegylated IFN-α2a monotherapy cleared HDV RNA. No patients treated with adefovir dipivoxil alone cleared HDV RNA at 48 weeks.[216]

Currently, no recommendations have been established regarding the use of IFN-α or pegylated IFN-α2b for the treatment of chronic HDV infection in children. A trial in seven children in Greece treated with IFN-α in a dosage of 3 million units/m^2 of body surface area three times a week for 1 year yielded disappointing results. All remained anti-HDV IgM positive, and four of the seven had persistent HDV RNA in serum. A significant reduction in serum aminotransferase values was noted after 1 year of treatment, but there was no significant improvement in liver histology.[48] A study of eight children from Germany also found no effect of IFN-α on replication of HDV. However, serum aminotransferase values improved and children underwent earlier anti-HBe seroconversion compared with historical controls.[180] Lamivudine has been shown to have no effect on either HDV viremia or liver disease activity in chronic HDV infection.[165]

Some children and adults require liver transplantation for management of end-stage HDV-associated liver disease. Patients coinfected with HDV and HBV have lower rates of HBV infection of the allograft than do those in patients with isolated HBV infection. These data were reported in a series of 58 patients with HBV infection, of whom 25 also had HDV infection and who underwent liver transplantation between 1984 and 1996 in Belgium. Fifty-two patients survived longer than 3 months, and median follow-up was 74 months. HDV infection improved survival at 5 years: 96 ± 4 percent compared with 63 ± 10 percent for those infected with HBV alone.[128] As yet, no explanation has been given for the better outcome of transplantation in individuals who have both HBV and HDV infections. Administration of HBIG is required before and after transplantation, as in those patients with HBV infection alone.

IMMUNOPROPHYLAXIS

Passive or active immunization specifically against HDV infection is not available. HDAg itself is highly immunogenic, but antibodies are not neutralizing. Description of a T-cell response to several HDV epitopes in individuals with less severe disease activity has stimulated speculation about possible vaccine development, but studies are preliminary. A DNA-based HDV vaccine successfully induced cellular responses in an animal model and also was successful when used with a HBV vaccine.[90] A trial of vaccine derived from B-cell epitopes of HDAg and HDAg p24 expressed in *Escherichia coli*, yeast, or baculovirus in woodchucks provoked a specific antibody response but did not protect against HDV superinfection.[64]

At the present time, individuals with chronic HBV infection, who are the same people at risk for acquiring HDV, cannot be protected from HDV infection except by avoidance of high-risk behaviors and exposures. However, prevention of HBV infection in susceptible individuals will prevent HDV coinfection and will be the most important mechanism for decreasing the prevalence of HDV infection in a population. The current strategy aimed at decreasing susceptibility to HBV infection by universal immunization of neonates and catch-up immunization of older children and adolescents should reduce substantially the risk for subsequent development of HDV infection during young adulthood. In Italy, the decrease in HDV prevalence in those with chronic HBV infection from 23 percent in 1987 to 8.3 percent in 1997 has led to speculation that chronic hepatitis D may be a "vanishing disease."[66]

DNA VIRUSES

SUBSECTION 5 *HERPESVIRIDAE*

CHAPTER 157

Herpes Simplex Viruses 1 and 2

Kathleen Gutierrez • Benjamin Pinsky • Ann M. Arvin

Herpes simplex virus (HSV) types 1 and 2 are in the family of nine human herpesviruses, which also includes cytomegalovirus (CMV), Epstein-Barr virus (EBV), varicella-zoster virus (VZV), and human herpesviruses (HHV) types 6A, 6B, 7, and 8.

HSV-1 is the prototype of the α-herpesvirus subfamily, which includes HSV-2 and VZV.[317] These viruses are ubiquitous and neurotropic and establish latency in sensory ganglia; persistence is associated with periodic reactivation and reappearance of infectious virus at mucocutaneous sites. Most individuals infected with HSV-1 and HSV-2 do not have clinical manifestations, either at the time of initial acquisition or during episodes of reactivation. When HSV-1 or HSV-2 causes disease, the illness may range from minor, such as "fever blisters," to life threatening, as exemplified by HSV encephalitis or neonatal disease. Proper management of HSV-1 and HSV-2 infection depends on clinical recognition of the common and atypical syndromes caused by these viruses, knowledge of laboratory methods that are useful for proving the diagnosis, and early and appropriate antiviral therapy.

THE VIRUSES

HSV-1 and HSV-2 virions consist of an icosahedral protein capsid enclosing a core of double-stranded DNA, surrounded by a protein tegument, and enclosed in a lipid-containing envelope.[317] The genomic DNA of HSV-1 and HSV-2 has substantial sequence homology (approximately 50%), but the viruses also have unique sequences that encode variant proteins, and they differ biologically in their patterns of replication in vitro and in vivo. Tegument proteins are located between the capsid and the viral envelope. The envelope has glycoproteins that are important targets of the humoral and cellular immune responses (gB, gC, gD, and gG). The glycoproteins gE and gI function as immunoglobulin (Ig) Fc receptors. Other glycoproteins include gH and gL, which form a complex with gB that plays a role in cell entry and spread; gK, which is required for viral exocytosis; and gM, which has a role in capsid envelopment and exocytosis. These glycoproteins are found in both HSV-1 and HSV-2 and exhibit a high degree of amino acid similarity. The gG of HSV-2 is larger than its HSV-1 homologue and has unique sites that are recognized by virus-specific host responses. Both forms of HSV can infect either oral or genital sites; however, HSV-1 usually causes infections of oral mucocutaneous sites and most genital mucocutaneous infections are caused by HSV-2.[118,317] HSV-1 is more likely to recur at oral sites, and HSV-2 reactivates more frequently in the genital area, even in persons who were infected initially at both oral and genital sites with HSV-1 or HSV-2.[220]

HSV attaches to and penetrates cells via gB and gD through specific cell surface herpes family receptors. This

process also involves gH and gL. The herpes family coreceptors belong to the tumor necrosis factor family (Hve-A), the immunoglobulin superfamily of receptors (nectins), and the 3-*O*-sulfated heparin sulfates.[317] After the virion enters the cell, an orderly expression of immediate early, or α, genes occurs that triggers viral gene transcription and inhibits host cell function; early, or β, viral genes that encode regulatory proteins and DNA replication enzymes, including thymidine kinase and viral DNA polymerase; and finally, late, or γ, genes that encode structural proteins. Replication of viral DNA and accumulation of structural proteins allow assembly of the virion capsid in the cell nucleus and envelopment by modified cellular membranes that are incorporated into the virion envelope during virion egress. Infectious virions are released from the infected cell or can spread to adjacent cells via membrane fusion.

Human HSV replicates in tissue culture cells derived from many mammalian species and various laboratory animals, including rodents, rabbits, and primates. Lack of restriction of the host range distinguishes HSV-1 and HSV-2 from the other human herpesviruses. HSV-1 and HSV-2 replication progresses rapidly in cell culture and causes characteristic focal cytopathologic effects. Confirmation that these effects are caused by HSV can be accomplished by staining the infected cells with specific antisera or monoclonal antibodies that differentiate HSV-1 from HSV-2 and from other viral pathogens.

Like other herpesviruses, HSV-1 and HSV-2 have gene products that inhibit intrinsic cellular responses that interfere with replication and facilitate the avoidance of immune surveillance during primary infection, latency, and reactivation. Among others, these mechanisms include elaboration of virally encoded IgG Fc receptors formed by gE/gI and complement receptors that bind host immune components; downregulation of major histocompatibility complex (MHC) class I antigen, which prevents recognition of infected cells by $CD8^+$ T cells; interference with upregulation of MHC class II molecules by interferon-γ, which inhibits $CD4^+$ T-cell–mediated adaptive immune responses; and inhibition of the lytic activity of natural killer cells.[317]

TRANSMISSION

Infectious HSV-1 and HSV-2 virions are released into the oral or genital secretions of infected but asymptomatic persons who are experiencing primary or recurrent infection. This phenomenon is referred to as viral excretion or *viral shedding* and results in periodic opportunities for the virus to be transferred to susceptible contacts. Most HSV-1 and HSV-2 transmission is caused by silent infections, and transmission occurs with equivalent frequency regardless of whether the individual who is shedding the virus has ever had symptoms of oral or genital herpes.

Although HSV-1 and HSV-2 are highly infectious after inoculation of mucocutaneous sites, they are not transmitted casually from person to person. The enveloped virions are unstable outside mammalian cells, and close interpersonal contact is required for transfer of infectious virus particles. In most circumstances, transmission requires direct apposition of infected with uninfected mucous membranes or skin during intimate contact such as kissing or sexual contact. Outbreaks associated with gingivostomatitis have occurred at daycare centers.[344] If uninfected exposed skin or mucous membranes are damaged, the risk for transmission appears to be enhanced. Although skin is less susceptible to direct inoculation than the mucous membranes are, transmission via inoculation of skin may be increased by local trauma. For example, affected areas are more susceptible in burned patients[135] and infants with diaper rash. Children with eczema are at risk for contracting serious disseminated HSV infections (Kaposi varicelliform eruption).[13,430] Transfer of HSV-1 between wrestlers (herpes gladiatorum)[351] and between rugby players (herpes rugbeiorum or "scrum-pox")[353] probably takes place after the abrasion of saliva-contaminated skin. One outbreak at a wrestling camp involved 60 of 175 participants.[36,76] Health care workers may acquire HSV infections of the paronychial region (herpetic whitlow), presumably from direct contact of ungloved hands with oropharyngeal secretions.[142,319] Medical personnel can transfer HSV to their patients. Children acquire HSV whitlow in the course of primary HSV-1 gingivostomatitis through nail biting or thumb sucking. When herpetic whitlow develops in persons who are not health care workers, HSV-2 is a common cause and often is associated with primary genital HSV infection.[144] The usual route of transmission to neonates is by exposure during passage through an HSV-infected birth canal. Genital and anal HSV infections are transmitted through direct contact with infected genitalia or from orogenital or oroanal contact.

Newly acquired HSV-1 and HSV-2 infections are associated with shedding of high titers of infectious virus, regardless of whether the individual is symptomatic. In addition, active recurrent HSV-1 or HSV-2 lesions contain substantial titers of virus, which may increase the likelihood of transmission occurring during close contact with a susceptible individual.

The incidence of acquisition of HSV-2 is 5 to 15 percent per year in individuals who are HSV-1 and HSV-2 seronegative or HSV-1 seropositive but HSV-2 seronegative and whose sexual partners have recurrent genital herpes.[257,258] In studies of discordant couples, transmission occurred in 10 percent of partners, with higher transmission from men (17%) than from women (4%). In women lacking antibodies to HSV-1 and HSV-2, the rate of transmission was 32 percent; if they had antibodies to type 1, the rate was 9 percent.[257] Studies of patients by HSV-2–specific serology show that many individuals remain uninfected despite having long-term contact with a person who is infected with HSV-2.[215] The extent to which HSV-1 immunity protects against HSV-2 infection is not clear, but the evidence is that symptoms of new HSV-2 infection may be prevented if the exposed individual has HSV-1 immunity, whereas subclinical infection frequently is not blocked.[46,60] Information about whether HSV-1 or HSV-2 acquired earlier interferes with the acquisition of infection by unrelated HSV-1 or HSV-2 strains is limited, but a few individuals with multiple sexual partners have been found to shed HSV-2 viruses that are genetically distinct.

HSV has been isolated from the hands of patients with oral lesions and has been shown to persist for several hours on inanimate objects or in distilled water. Nonetheless, inanimate sources have not been implicated as important reservoirs of HSV persistence and spread.[275,402] HSV transmission from transplanted organs[119] and inseminated donor sperm has been reported.[262]

When HSV-1 and HSV-2 shedding has been evaluated prospectively in seropositive individuals with or without a history of symptoms, the usual frequency of detection of virus in oral or genital secretions is 1 to 2 percent.[15,317] In patients with known genital herpes, silent excretion has been documented as often as 10 percent of the time when they appear to be lesion free. Twelve percent of women with primary HSV-1 genital infection and 18 percent with primary genital HSV-2 infection subsequently shed virus asymptomatically, especially in the first 3 months after resolution of the primary infection.[204] Two percent of women attending a sexually transmitted disease clinic shed HSV-2 asymptomatically.[213] In partner studies, 70 percent of HSV-2 transmissions were associated with sexual contact during periods of asymptomatic viral shedding.[258]

Polymerase chain reaction (PCR) is considerably more sensitive than is culture for detection of HSV on mucosal surfaces, and the use of this technology has improved understanding of the extent of HSV viral shedding. However, it is important to recognize that the detection of segments of the viral genome by PCR does not necessarily mean that infectious virus is present. PCR detects subclinical shedding of HSV-2 on 20 to 25 percent of days. Factors that influence the magnitude and frequency of shedding include the site of infection, immune status of the patient, and time of acquisition of the virus.[324] Previous studies using viral cultures rarely reported isolation of HSV-2 from the mouth, but recent quantitative PCR studies detected asymptomatic oral HSV-2 reactivation from 40 percent of men with HSV-2 genital herpes. Oral HSV-2 shedding frequently is concurrent with genital HSV-2 shedding.[197]

Investigation of HSV-1 transmission is less extensive, but the high prevalence of asymptomatic HSV-1 infection in the population and its acquisition in early childhood suggest a similar pattern of spread by exposure to virus present in oral secretions from asymptomatic individuals.

Both HSV-1 and HSV-2 can be transmitted to a neonate. Approximately 4 percent of neonatal herpes cases are acquired in utero, 86 percent around the time of birth, and 10 percent postnatally. Three fourths of natal/postnatal cases of neonatal herpes infection are caused by HSV-2, and the remainder are caused by HSV-1 strains.[283] Virtually all neonatal HSV-2 infections probably are acquired from mothers having an active genital herpes infection by contact with infected genital secretions at or during delivery from an asymptomatic mother who acquired her first episode of genital herpes infection in the third trimester or near the time of delivery.[283,384,441,451] The majority of neonates with HSV appear to acquire the infection by contact with infected genital secretions at or during delivery from an asymptomatic mother who acquired her first episode of genital herpes infection in the third trimester or near the time of delivery.[51,52,55-57] Because 60 to 80 percent of mothers who have newborns with HSV have no signs or symptoms of genital herpes at the time of labor and delivery and have a negative past history of genital herpes or contact with a partner who had a genital vesicular rash, some experts recommend routine serologic screening of pregnant women and their partners to identify potential at-risk mothers.* Neonates with HSV-1 infection can acquire the virus from several sources: maternal genital tract, oral contact with mother, breast lesions,† oral herpes in the father or other family members,[117,384,452,453] or health care–associated transmission from other infected infants or health care workers.[161,241] Although HSV-1 cold sores and asymptomatic oral shedding may be common findings in nursery personnel,[170,171] transmission to a neonate from this source appears to be rare.[316,405] Male neonates may also contract HSV infection after out-of-hospital ritual circumcision.[80] In a recent report, 11 neonates were reported infected with HSV after orthodox Jewish ritual circumcision that included metzitzah B'peh, a practice in which the circumciser uses his mouth to apply direct orogenital suction to the newly circumcised penis to clean the blood away from the wound.[80]

EPIDEMIOLOGY

Understanding HSV epidemiology requires distinguishing between the prevalence of infection, which is high, and the frequency of HSV-related disease, which is low. These viruses maintain their persistence in the human population through their capacity to persist and reactivate in the individual host. The prevalence of HSV-1 and HSV-2 is a consequence of efficient transmission to susceptible close contacts and the continuous presence of a large pool of infected persons in the population. Because HSV-1 and HSV-2 are not cleared after primary infection but instead establish latency and reactivate frequently in an infected host, opportunities for viral spread to new susceptible persons are common. Seroepidemiologic studies have shown that HSV infections are found in all human populations, even in the most remote and isolated communities. HSV-1 and HSV-2 have no seasonal pattern because the mechanism of transmission is by intimate contact, which occurs year round. Individuals who have been infected with HSV-1 or HSV-2 remain a reservoir for infectious virus throughout their lifetimes and, as intermittent shedders, are sources of virus that spreads to susceptible contacts. Most transmission is from asymptomatic infection, and most acquisition is asymptomatic. For example, the rate of subclinical shedding of HSV-2 in individuals with no reported history of genital herpes was similar to that in subjects with such a history (3.0% vs. 2.7%).[420] Shedding of HSV-1 in oral secretions is equally prevalent.

When symptoms of a new HSV-1 infection do occur, the source of the infection rarely is identified because the susceptible individual usually has many infected contacts.

The first symptomatic episodes of HSV-1 or HSV-2 often represent reactivations of earlier infections.

The average age at acquisition and the prevalence of HSV-1 and HSV-2 infection are influenced by the virus type. Although neonatal HSV infections are usually acquired from maternal genital infection and usually are caused by HSV-2, HSV-1 acquisition predominates in childhood. Depending on social and economic factors, 20 to 40 percent of young children are seropositive by the time they reach 5 years of age, with higher rates of acquisition in lower socioeconomic groups, non-Hispanic blacks, and children born outside the United States.[450] Earlier acquisition of HSV-1 may be influenced by whether the mother, or other major caregivers, has HSV-1 infection. Attendance at child care centers, which brings children together in close contact, may increase the likelihood of acquiring HSV-1 at an earlier age.[218,344] Acquisition of HSV-1 continues with age at an average rate of 1 to 2 percent per year throughout the childhood and adult years; by later ages, 70 to 90 percent of individuals have been infected by HSV-1.[360] Seroepidemiologic studies of higher socioeconomic groups have reported HSV-1 infection in 30 to 46 percent of university students.[141]

The prevalence of HSV-2 is highly variable and depends on the country, region, sex, age, population subgroup, and whether a population is "high risk."[357] Because transmission of HSV-2 is associated with sexual activity, the prevalence of HSV-2 begins to increase with adolescence. Now that serologic methods can be used to differentiate HSV-1 and HSV-2 infection, the seroprevalence of HSV-2 in adults has been shown to range from 20 to 60 percent. Continuing comprehensive investigation of HSV-2 epidemiology in the United States by the National Health and Nutrition Examination Survey (NHANES) documented a 30 percent increase in prevalence from the 1970s to the 1990s, which resulted in HSV-2 infection in approximately 20 percent of adults in the period between 1988 and 1994.[75,134,186] Since that time, HSV-2 seroprevalence has decreased to approximately 16% in individuals 14 to 49 years of age.[78] High HSV-2 infection rates are documented in higher as well as lower socioeconomic groups.[46,213,215,382] Rates are consistently higher in women, non-Hispanic blacks, and individuals with multiple sexual partners.

Changes in the epidemiology of symptomatic HSV-2 infection have been suggested by rising numbers of medical visits for genital herpes. The extent to which the increase in symptomatic cases of HSV-2 infection reflects a true increase in the prevalence of HSV-2 or a higher likelihood that HSV-2 infection will result in symptoms is not certain. The decrease in the number of young adults with HSV-1 infection acquired in childhood could be associated with loss of cross-reactive HSV immunity and an increased risk for the development of symptomatic genital herpes. A higher risk for contracting genital HSV-2 infection is associated with lower socioeconomic status, early age at first intercourse, increased numbers of sexual partners, female sex, previous marriage, urban living, black race, and incidents of trichomoniasis, bacterial vaginosis, and other sexually transmitted diseases.[134,149,187]

A retrospective analysis of genital HSV cultures obtained from a group of college students over the course of a 9-year period showed that HSV-1 is an increasingly common cause of genital herpes in some populations in the United States. In this particular population, HSV-1 accounted for more than 70 percent of positive genital cultures by the end of the study period, as compared with approximately 30 percent at the beginning.[314]

Symptomatic disease occurs after newly acquired HSV infection at an estimated incidence of 10 to 20 percent or less. However, silent infections can give rise to symptoms that appear months or years later as a result of viral reactivation. The epidemiology of HSV-1 or HSV-2 reactivation as a cause of symptomatic illness depends on the prevalence of these infections in the population as a whole, but it also is influenced by host factors that perturb the balance between the virus and the infected individual. For example, HSV-related symptoms may be triggered by exposure to sunlight (ultraviolet), febrile illnesses, immunosuppression from illness or necessary therapies, and other variables. These variables are cofactors that affect the frequency of HSV-related disease within the infected cohort but not the epidemiologic pattern of infection.

HSV infections may be transmitted from the mother to her fetus and neonate. Fulminant or disseminated primary HSV disease may occur in pregnancy, but whether it develops more often than in nonpregnant women is not clear.[221] A review[292] of seven such cases revealed (1) infection during the third trimester in all; (2) four beginning as a genital HSV infection and three as oral disease; (3) hepatitis in six, encephalitis in two, and pancreatitis in two; (4) maternal death in three (43%)—two from hepatitis and one from encephalitis; and (5) three instances of fetal death—each secondary to severe maternal systemic illness rather than direct infection with HSV. Postpartum HSV endometritis may also occur and result in disseminated infection in both mother and neonate.[130,253]

An increased rate of spontaneous abortion occurs in women with primary genital herpes during early pregnancy, regardless of socioeconomic status.[55,164,165,269] Premature delivery does not occur more commonly in prospectively monitored women with recurrent genital herpes,[164,283,409,447] but most reports of neonatal herpes cases find a greater preponderance of premature infants than in the general population.[283,441,452] This finding, however, may reflect a higher susceptibility of premature infants to HSV infection secondary to a lack of transplacentally acquired IgG neutralizing antibodies rather than being a cause of the prematurity. Recurrent genital herpes in middle-class pregnant women is no more severe or frequent than in nonpregnant ones,[164,409,447] but older studies demonstrated more frequent and longer episodes in women of lower socioeconomic groups.[269,276] Between 74 and 88 percent of middle-class pregnant women with a history of genital herpes had at least one clinical recurrence during an observed pregnancy.[164,409,447] A mean of 2.7 to 3.0 episodes occurred during gestation, and HSV was isolated from lesions in 56 to 75 percent of the recurrences and in 0.6 to 12 percent of concomitant cervical cultures obtained during the recurrence. Asymptomatic

shedding of HSV from the cervix, either between clinical recurrences or in a history-positive woman with no episodes during the observed pregnancy, was detected in 0.5 to 2.3 percent of the cultures obtained. Importantly, the presence of HSV shedding during the latter weeks of pregnancy was not predictive of shedding at the time of delivery.[15,447]

The number of cases of neonatal herpes occurring in the United States each year is far less than one would expect from the probable number of pregnancies complicated by genital herpes. Of the 3.5 to 4 million annual pregnancies, 7,000 to 200,000 of these women have genital herpes at some time during the pregnancy and 3,500 to 14,000 have positive HSV cultures at the time of delivery.* The actual number of cases of neonatal herpes per year in Seattle and Atlanta (0.1 and 0.3 per 1000 live births, respectively) would project to a national estimate of 350 to 1,050 per year in the United States.[384] An estimate of the incidence of neonatal HSV is between 1 in 3,000 and 1 in 20,000 and may vary with the demographics and geographic location of the population. Because asymptomatic HSV infection of the neonate rarely, if ever, occurs, subclinical cases or missed diagnoses probably do not account for the differences between the estimated number of maternal and neonatal infections. More likely, neonatal infection rates in the neonates of mothers with genital herpes are far lower than currently assumed, possibly because of the preventive measures used. The estimated infection rates quoted most often currently are (1) a 33 to 50 percent rate for infants vaginally delivered by mothers with primary genital herpes, (2) a 3 to 5 percent rate for infants vaginally delivered by mothers with recurrent lesions, and (3) less than 3 percent for those delivered by mothers with recurrent asymptomatic shedding at the time of delivery.† In the early 1970s,[269] the following neonatal infection rates in neonates born to mothers with genital herpes during pregnancy were reported: (1) 33 percent in mothers with primary disease after the 32nd week of gestation, (2) 3 percent in mothers with recurrent episodes after 32 weeks, and (3) 42 percent in mothers with virus-positive lesions at the time of delivery (primary vs. recurrent episodes not specified). More recent studies have determined a significant risk for neonatal herpes occurring in neonates born to mothers with asymptomatic shedding at the time of vaginal delivery: 33 percent with subclinical first episodes and 0 to 3 percent with recurrent shedding.‡ Accurate knowledge of the actual neonatal infection risk is important for making decisions about management (e.g., cesarean section, prophylactic antiviral therapy). Researchers and experts have estimated that as many as 75 percent of neonates with HSV disease are born to mothers with no history or clinical findings suggestive of active HSV infection during pregnancy, labor, or delivery.[5,52,69,70,71]

Several factors influence the risk for acquiring neonatal herpes and the severity of neonatal disease once the infection develops. The greater risk for transmitting neonatal infection by mothers with primary, as opposed to recurrent, vesicular or ulcerative lesions at the time of delivery is well established. Also, a woman with virus-positive recurrent lesions at the time of delivery is likely to be at greater risk than is a woman who is asymptomatic and shedding virus identified by HSV surveillance cultures. Other aspects of the anatomic site and the severity of maternal genital herpes also may be associated with a greater risk for development of neonatal disease: (1) maternal cervical as opposed to vulvar or buttock skin involvement—resulting in more virus being shed into vaginal secretions; (2) multiple as opposed to single vesicles or ulcers—again, more virus from multiple lesions; (3) higher titer of virus in vaginal secretions—cultures positive sooner or more intensely positive in the diagnostic virology laboratory; and (4) longer duration of fetal exposure to infected vaginal secretions because of prolonged rupture of membranes or of fetal scalp monitors.[92,281-283]

Investigations by Yeager and associates[452,453] indicate that no anti-HSV antibody or a low titer of such antibody in maternal and neonatal serum is associated with a greater risk for acquisition of neonatal infection and more serious disease and that high-titer antibody is associated with a lower risk. Studies of HSV antibody titers in neonates do not show an association between antibody titer and outcome of disease. More investigations are required, therefore, to determine the potential protective role of maternal transplacental anti-HSV antibody.

Premature infants have accounted for 40 to 50 percent of cases of neonatal herpes,[394,434,444] in contrast to the usual prematurity rates of 6 to 18 percent reported in the general maternal population. Whether the increased frequency of prematurity among neonates with herpes indicates a greater propensity of mothers with genital herpes to deliver prematurely or a greater susceptibility of premature infants to HSV infection is not known. Premature infants appear more likely to have a fatal outcome.[71,434,435]

Instrumentation of the neonate, particularly scalp electrodes for fetal monitoring, is known to increase the risk for acquiring neonatal HSV infection.[122,195,287] Mortality rates appear to be higher in neonates with HSV-2 than in those with HSV-1 infection, probably because of the greater proportion of HSV-2–infected infants with dissemination.[435] In neonatal herpes survivors, neurologic damage occurs much more frequently in infants with HSV-2 infection than in those with HSV-1 infection.[96,435] Infants with disseminated infection (liver, lungs, adrenals), with or without central nervous system (CNS) involvement, have the highest mortality rates (70% to 80%); those with encephalitis have only intermediate rates (30% to 40%); and those with infection limited to the skin, eye, or mouth have the lowest rates (0%).[444] Rarely, neonatal HSV has been implicated as a cause of sudden unexpected death in infancy.[426]

The prevalence of HSV infection in febrile neonates presenting to an acute pediatric emergency treatment center appears similar to that of bacterial meningitis, suggesting that HSV infection should be in the differential of neonatal fever and evaluated accordingly.[69-71] Factors associated with neonatal HSV infection in febrile or hypothermic neonates presenting to acute care centers

include history of peripartum maternal fever, history of maternal primary HSV infection, prematurity, vaginal delivery, neonatal seizures, vesicular rash, respiratory distress, thrombocytopenia, elevated hepatic enzymes, and CSF pleocytosis.[69-71] Because the presentation of neonatal HSV is nonspecific, and delay in diagnosis and treatment is associated with significant morbidity and mortality, some experts recommend all neonates younger than 21 days of age receive evaluation for HSV infection and early empirical treatment with acyclovir.[69-71,246]

PATHOGENESIS AND PATHOLOGY

HSV-1 and HSV-2 exhibit particular tropism for cells of ectodermal origin, including skin and neuronal cells. Initial viral replication is thought to occur at the portal of entry, usually in mucous membranes or skin. In symptomatic cases, the incubation period for primary infection appears to vary from 2 to 20 days. In contrast to varicella, HSV viremia is difficult to detect by culture in a normal host, although it may be found in some immunocompromised patients.[158,370] HSV DNA in plasma and peripheral blood mononuclear cells in HSV-infected neonates has been detected with PCR techniques.[111] HSV DNA has also been detected in approximately 25% of patients with confirmed primary genital HSV infection. Women are more likely to be viremic than men, and viremia is detected more frequently early after infection.[188]

If mucocutaneous lesions are induced during primary or recurrent infection, the pathologic cell changes caused by HSV-1 or HSV-2 replication include cytoplasmic enlargement and nuclear alterations. Cell fusion may lead to the formation of multinucleated giant cells. The nuclei of infected cells often have eosinophilic intranuclear inclusions and marginated nuclear chromatin. As the cells manifest injury, a local inflammatory response ensues, intercellular edema develops, and vesicles form. The vesicles become visible as they enlarge and usually are surrounded by an erythematous margin. At later stages, the vesicles become pustular and then dry and crust. HSV lesions typically are superficial and do not scar. Vesicles that form on mucous membranes are transient, with rapid sloughing of the superficial layer, and are seen first as shallow ulcers.

HSV-1 and HSV-2 establish latency in neurons of the sensory ganglia by mechanisms that are as yet unidentified. The viruses persist in this latent state for various intervals, although frequent asymptomatic reactivation is common; reactivation induces viral replication with the production of infectious virus at mucosal or other sites. Persons who have recurrent HSV infections frequently describe tingling sensations, itching, and burning at the site of recurrence beginning several hours before the appearance of clusters of vesicles. Persons who have recurrent genital herpes may experience severe shooting pain in their legs and even urinary retention in connection with recurrence. Occasionally, recurrent HSV skin eruptions may occur in a zosteriform pattern in a distribution reflecting the sensory innervation of a particular dermatome.

Replication at the portal of entry appears to result in infection of sensory nerve endings, followed by transport of the virus to the cranial and dorsal root ganglia along neuronal axons. Latency is established regardless of whether the primary infection is symptomatic, and it appears to be an invariable consequence of HSV infection with either virus type.[27,315,317] HSV-1 and HSV-2 persist in neuronal cells of the sensory ganglia, with substantial numbers of these cells harboring latent virus, as demonstrated by the detection of latency-associated transcripts. The latency-associated transcripts overlap the viral genes *ICPO* and *ICP34.5* in an antisense direction.[97,317,372] The role of these transcripts in the establishment or maintenance of latency remains to be clarified. The presence of latency-associated transcripts appears to be necessary for establishment of latency and efficient reactivation of viral production in some animal models in vivo.[294] Viral particles are not produced in latently infected cells. HSV-1 persists most predominantly in the cranial nerve ganglia, whereas HSV-2 latency occurs in the lumbosacral ganglia. Cocultivation techniques have been used to recover HSV from the dorsal root ganglia innervating the areas of skin in which persons have experienced recurrent herpes lesions. HSV-1 has been found in trigeminal ganglia, and HSV-2 has been recovered from sacral ganglia.[29] Once latency is established in the sensory ganglia, antiviral drugs cannot eradicate the latent virus from infected neurons. Because the latent virus does not multiply, it is not susceptible to drugs that affect viral DNA synthesis, such as acyclovir. When reactivation is triggered, HSV-1 or HSV-2 is transported back down axons to mucocutaneous sites, where they replicate and release infectious virus into secretions.[27,99,315,317] Individuals with symptomatic recurrent HSV infections almost always have HSV lesions in the identical or a directly adjacent site. Reactivation is not prevented by adaptive immunity, although whether symptoms occur and whether the virus disseminates may be influenced by the host response.

The stimulus for reactivation of latent virus may be provided by iatrogenic or naturally occurring episodes of immunosuppression and by endocrine (e.g., menstruation) or exogenous (e.g., trauma, sun, acupuncture, emotional stress) factors. Ultraviolet irradiation of the usual site of recurrence of persons who have a history of recurrent oral herpes reliably induces recurrence either quickly (within 48 hours) or 2 to 7 days later.[361] Skin subject to recurrent HSV infection has been transplanted elsewhere on the body and exchanged with skin taken from the site of graft placement and previously not involved in HSV infections. Subsequent recurrence of HSV infection was found to be localized to the original site, not to the original skin. These studies and others strongly suggest that latent virus does not reside in skin cells.

Primary HSV infection elicits humoral and cellular immunity, which can be detected shortly after the appearance of lesions in individuals in whom symptoms develop. Based on animal models and some human studies, the initial host response is mediated by innate, nonspecific mechanisms, followed by the acquisition of virus-specific adaptive immunity.[205] The nonspecific response consists of mobilization of polymorphonuclear leukocytes and monocytes to the site of infection, release of interferon-γ and other cytokines, and activation of macrophages and natural killer cells. The innate response is followed by

the production of antiviral antibodies that can be detected 2 to 12 weeks after infection occurs. HSV-specific antibodies mediate neutralization of virus, complement fixation, and cellular or complement cytotoxicity. Induction of specific cellular immunity is detected by measuring T-cell recognition of HSV proteins in proliferation and cytotoxicity assays and production of interleukin-2 and interferon-γ. Failure of virus-specific, cell-mediated immunity to develop, as may occur in neonates and children with genetic immunodeficiencies, immunocompromised children, and other high-risk populations, can be associated with life-threatening dissemination of HSV-1 or HSV-2. Disseminated HSV can infect and destroy cells in many organs (e.g., the lungs, liver, adrenals, and brain), with multiple- organ hyperinflammation leading to massive apoptosis, with catastrophic effects. It is likely disseminated HSV in the neonate and in the older child and adult causes a systemic inflammatory response syndrome that often causes a fatal outcome. One case report reported the sequential changes of hyperinflammation in a neonate with disseminated HSV disease. As the HSV DNA copies rose in the patient's serum, an increase in the biomarker concentrations of first high-mobility group box 1 and then cytochrome c was observed. Anti-inflammatory interventions with prednisolone, high-dose immunoglobulin, blood exchange, and high dose acyclovir were used for treatment, and the patient survived.[267] A small group of immune-seronegative individuals with HSV-specific T-cell responses has been described. None of these individuals had clinical symptoms of oral or genital HSV. All had exposure to HSV-2–positive sexual partners, but HSV was never isolated by culture or PCR assay from these exposed individuals, even after extensive sampling over a prolonged period.[300] Studies to determine whether genetic immunologic determinants of disease or mutations in HSV entry receptors alter susceptibility to HSV infection are in progress.[379]

Symptomatic HSV-1 and HSV-2 recurrences are less severe than are primary lesions in immunologically intact persons. In persons previously infected with one type of virus (e.g., HSV-1), new infections with the second type (e.g., HSV-2) more often are silent, or the symptoms are less severe than in a host who has never been infected with either virus. When reinfection with unrelated strains has been identified, symptoms also have been mild and, without molecular analysis of viral DNA, would be attributed to reactivation of endogenous virus.[62] The immune response to symptomatic reactivation is not associated with a significant increase in the production of antibody, although fourfold rises and reemergence of IgA and IgM antiviral antibody may occur. Natural killer cell activity and cytokine production increase. Relative defects in these and HSV-specific T-cell responses may predispose the individual to frequent or severe symptomatic recurrences. A cohort of patients with severe eczema, sinopulmonary infections, elevated serum IgE levels, eosinophilia, and cutaneous viral infection (including severe HSV) caused by DOCK8 deficiency has been described.[455] Patients who have diseases or are being treated with agents that reduce cell-mediated immunity, such as those undergoing antitumor chemotherapy or individuals with acquired immunodeficiency syndrome (AIDS), often have frequent HSV recurrences that are longer in duration and more severe, but dissemination rarely occurs.

Viral encephalitis is the most severe consequence of HSV infection in an otherwise healthy host. HSV-1 is the pathogen in almost all these cases, and the pathologic mechanism is thought to be ascending infection along neuronal pathways from the cranial nerve ganglia to the brain.[104] Encephalitis may accompany or develop after primary HSV infection, but it also occurs as a consequence of reactivation of latent virus. When the virus reaches brain parenchymal cells, it replicates efficiently and induces widespread hemorrhagic necrosis and vascular compromise. The neuroimmune response to infection contributes to brain inflammation and subsequent sequelae. Activated glial cells (astrocytes and microglia) respond to HSV infection with the production of cytokines and chemokines.[245] HSV encephalitis has been associated with an acute-phase elevation in β_2-microglobulin, neopterin, interleukin-6, and interferon-γ in cerebrospinal fluid (CSF).[21,22] During convalescence, increased levels of soluble CD8, β_2-microglobulin, neopterin, and specific anti-HSV IgG have been detected. How these markers relate to the pathogenesis of disease has not been established.

Genetic heterogeneity involving a collection of inborn errors of immunity to HSV may predispose to herpes encephalitis. To date, signal transducer and activator of transcription–1 (STAT1), UNC93B, Toll-like receptor–3 (TLR3), and TNF receptor-associated factor–3 (TRAF3) deficiencies and nuclear factor-κB (NF-κB) essential modulator mutations have been found in a few children with herpes encephalitis.[20,67,456] Most recently, TIR-domain–containing adapter-inducing interferon-β (TRIF) deficiency has been reported in children with herpes encephalitis, demonstrating the importance of TRIF for the TLR3-dependent production of antiviral interferons in the CNS during primary infection with HSV-1 in childhood.[334] A recent genetic epidemiology survey suggests that childhood HSV encephalitis, although sporadic, may result from mendelian predisposition (from autosomal recessive susceptibility in particular), at least in some children.[1]

HSV may be transmitted to the neonate in utero either by a transplacental (congenital infection) or ascending route, at the time of birth (natal infection), or after birth (postnatal infection).[394] Congenital infection probably results from transplacental transmission of virus secondary to leukocyte-associated viremia in a mother with genital herpes, but no direct evidence supports this hypothesis. HSV-2 viremia has been documented in two women with primary genital herpes.[189] A report of 13 neonates with intrauterine HSV infection indicated that primary genital herpes was present during pregnancy in four mothers, recurrent disease was present in one, and no history of genital herpes was elicited in the remaining eight.[356] In the fetus, HSV appears to be transmitted directly from the placenta through the bloodstream to target organs. Because of the known tropism of HSV for the CNS, one is not surprised that most infants with congenital infection have evidence of brain involvement at birth.[356] Intrauterine infection also may occur by an ascending route from an infected maternal genital tract,

and such transmission is supported by the development of clinical signs of HSV infection in the first 5 days of life.

The natal infection presumably is acquired secondary to aspiration of infected vaginal secretions into the nares, oropharyngeal cavity, conjunctivae, and upper respiratory tract of the infant. Other portals of entry for natal infection include the scalp, skin, and umbilical cord. In postnatal HSV infection, no evidence supports the genital tract as a source of virus. Most postnatally acquired infections appear to result from contact with saliva from persons with oral herpes or with virus carried on the hands of personnel. After natal or postnatal acquisition of HSV occurs, initial replication of the virus occurs at the portal of entry, which most often may be the conjunctivae or oral mucosa, with subsequent viremic dissemination to viscera. Involvement of the CNS occurs either from hematogenous spread to the brain in infants with disseminated disease, which results in meningoencephalitis and multiple areas of cortical hemorrhagic necrosis, or from retrograde axonal transport of the virus to the CNS from localized, superficial replication in the skin, eye, or mouth.

CLINICAL MANIFESTATIONS

Most HSV-1 and HSV-2 infections do not cause symptoms, but when infection is symptomatic the clinical manifestations usually are self-limited and not severe. If symptoms occur, the disease associated with primary infection tends to be much more extensive than are the minor, localized lesions at mucocutaneous junctions caused by viral reactivation. Nonetheless, prospective studies document that new HSV infections can be as mild as symptomatic recurrences, and, as a result, definitive differentiation of primary from recurrent infection is not possible with clinical criteria.

Gingivostomatitis

Gingivostomatitis is the most common form of HSV-induced primary illness in children. A history of such symptoms has been reported in as few as 1 percent to as many as 31 percent of seropositive children, the higher percentage being from a study involving the Navajo Indians. It usually is seen in young children between 10 months and 3 years of age. In those younger than 10 months old, residual maternal antibody probably modifies or prevents the appearance of recognizable symptoms in association with primary HSV-1 infection. Although acute gingivostomatitis caused by HSV is a relatively infrequent occurrence, it is sufficiently common that most pediatricians are familiar with the condition and learn to distinguish this infection from herpangina.[286,317]

The illness begins with irritability and fever. Despite these systemic symptoms, HSV is not cultured from blood during this period[158]; however, investigators have detected HSV-1 DNA by PCR assay in whole blood or plasma early in the course of illness in approximately a third of young children with primary HSV-1 gingivostomatitis.[163] The infant usually refuses to eat and may refuse

fluids. Thereafter, vesicular lesions appear around and on the lips, along the gingiva, on the anterior tongue, and on the anterior (hard) portion of the palate (Figs. 157-1 and 157-2). The vesicles break down rapidly, and, when seen, lesions usually appear as 1- to 3-mm shallow gray ulcers on an erythematous base. The gums are erythematous, mildly swollen, and ulcerated. They may appear friable and bleed on contact. The child experiences extreme discomfort, will not eat, and, if fluids are refused as well, may require hospitalization to ensure that adequate hydration is maintained. The risk for dehydration is compounded by the fever that generally accompanies this syndrome. Vesicles often extend around the lips and chin or down the neck in an immunologically intact child. The child frequently has foul-smelling breath (fetor oris). The lesions bleed easily and may become covered with a black crust. The cervical and submental nodes usually are swollen and tender. The clinical signs continue to evolve

for 4 to 5 days, and the process of resolution requires at least an additional week. In an analysis of the natural history of HSV gingivostomatitis in 36 children, oral lesions persisted for an average of 12 days, most children had extraoral lesions, fever lasted for 2 to 6 days, and difficulty taking liquids was noted for 4 to 10 days. The duration of viral shedding was 7 days (range, 2 to 12 days).[7] Herpetic epiglottitis[45] and acute otitis media[84] are unusual complications.

HSV gingivostomatitis is differentiated from herpangina, a manifestation of enteroviral infection, by the location of ulcers in the anterior portion of the oropharynx. Herpangina generally causes posterior pharyngeal ulcers. In addition, unlike HSV infection, herpangina often has a more acute onset, a shorter duration, and seasonal occurrence.[286] Whereas enterovirus-associated hand, foot, and mouth disease can manifest as oral ulcers and a vesicular eruption on the distal portions of extremities, its bilateral distribution should differentiate it from HSV gingivostomatitis and concurrent HSV autoinoculation of a digit. Severe Stevens-Johnson syndrome (erythema multiforme) may mimic HSV infection, but the generalized macular rash accompanied by "bull's-eye" lesions is characteristic of erythema multiforme. Rarely, recurrent HSV infection can be associated with erythema multiforme (see later discussion). Impetigo may be confused with the lesions of HSV infection, and misdiagnosis is reinforced because colonization of skin by *Staphylococcus aureus* may be identified in bacterial cultures and be considered causative.

Parents and caregivers are familiar with "cold sores" or "fever blisters" but may not know that these lesions are caused by HSV. Because HSV infection may be thought of as a sexually transmitted disease, the physician is advised to anticipate confusion and anxiety when making the diagnosis of HSV oral infection and to address these concerns by explaining the normal mode of acquisition of oral HSV infection by young children.

In adolescents, primary HSV-1 infection can be seen initially as exudative pharyngitis.[255] Characteristic findings are shallow tonsillar ulcers with a gray exudate. HSV infection must be differentiated from streptococcal and Epstein-Barr virus infection and rarely from diphtheria, acute human immunodeficiency virus (HIV) infection, and tularemia-induced pharyngitis. In one study of college students of a higher socioeconomic level, HSV was the most common etiologic agent of acute pharyngitis (24%).[143] Another study of 613 college students with upper respiratory tract complaints documented an incidence of 5.7 percent with positive HSV cultures. Twelve of the 35 students with positive cultures had vesicular lesions on their lips, throat, or gums, and 29 of the 35 had a primary diagnosis of pharyngitis that was indistinguishable from other causes of pharyngitis.[255] In some cases, acute pharyngitis is caused by HSV-2; the symptoms and clinical course appear to be similar, and viral cultures are required to identify the type of infecting virus.

Vulvovaginitis

Primary herpetic vulvovaginitis occurs rarely in infants and children. HSV-1 may cause this clinical syndrome, perhaps if inadvertently introduced when the genital area is touched by a caregiver with HSV on the hands. Progression of the infection may be limited to a few lesions, or it may resemble symptomatic primary genital herpes caused by HSV-2. Obtaining material for culture to identify the type of infecting virus is important because HSV-1 infection is less likely to recur and HSV-2 infection may reflect sexual abuse of the child. Genital HSV infection in young children warrants a careful and sensitive appraisal of the circumstances that possibly led to the infection. Children infected with HSV-2 in the neonatal period have had genital lesions later in childhood.

Pediatricians are likely to encounter genital herpes in their adolescent patients. Reports on the incidence of genital herpes in which data are provided for subgroups of children and adolescents are limited, but a rate of 3 per 100,000 in the 10- to 14-year-old age group and 76 per 100,000 in the 15- to 19-year-old age group was reported in a Minnesota study of a predominantly white, middle-class population of northern European ethnicity.[85] Older NHANES studies reported the prevalence in 12- to 19-year-old subjects to be 5.6 percent.[134] Recent NHANES data (2005 to 2008) show a decrease in HSV-2 seroprevalence in this age group, most recently to 1.4 percent in 14- to 19-year olds.[451] In one report of 379 adolescents aged 14 to 19 years who were treated at a sexually transmitted disease or urban community clinic, 12 percent had HSV-2 antibodies and only 22 percent of these patients had a history of genital herpes. HSV-2 seropositivity correlated with black race or female gender but not with condom use, the number of sexual partners in the previous 2 months, or a previous history of a sexually transmitted disease, thus indicating that prevalence was related to demographic rather than behavioral variables.[380]

Prospective studies have documented that many infections are subclinical and that new genital HSV-2 infections have a wide range of manifestations.[228,258] Variation is common with respect to the extent and severity of lesions; whether the lesions are bilateral or localized; the presence or absence of systemic symptoms such as malaise, myalgia, headache, and fever; dysuria; and regional lymphadenopathy. Symptoms can be mild enough to suggest recurrent infection or may be those of severe, "classic" primary genital herpes. In such cases in adults, local genital symptoms include severe pain (in 95% of men and 99% of women), itching, dysuria (44% of men and 83% of women), vaginal or urethral discharge, and tender inguinal adenopathy (80%). The lesions begin as vesicles or pustules and progress to wet ulcers and then to healing ulcers with or without crusts (Figs. 157-3 to 157-5). Crusting usually occurs only on squamous epithelium. Lesions tend to last for 2 to 3 weeks (mean, 19 days) before complete healing occurs. They may spread in a wavelike fashion from the initial site to the thighs, buttocks, and urethra. Virus shedding generally persists for 1 to 2 weeks or longer. Some primary infections are associated with atypical lesions (e.g., fissures, furuncles, excoriations), and extragenital lesions, typically on the buttocks, may be observed.[38,213]

When evaluating potential primary genital herpes in a sexually active adolescent, the history may reveal recent contact with a partner who is known to have recurrent

genital herpes. When exposure can be documented, the incubation period is estimated to be 2 to 14 days. However, most episodes will not be associated with a known exposure. It is important to recognize that as many as two thirds of first-reported episodes of symptomatic genital herpes actually are caused by reactivation. The exposure may have occurred months or years before the signs of HSV-2 infection appear. In some adult series, 50 to 60 percent of persons without a history of HSV infection can identify symptoms consistent with previous infection after receiving education about the typical signs, but many have not had any previous episodes.[226] HSV-1 accounts for 5 to 25 percent of primary genital HSV infections in the United States. Up to 50 percent of cases diagnosed in other geographic areas, such as England and Japan, are caused by HSV-1. Indications are that HSV-1 is becoming a more common primary genital isolate in the United States. In recent years, HSV-1 has been isolated from genital cultures more often than HSV-2 has in some populations.[314] Patients with primary HSV-1 genital infection occasionally exhibit lesions elsewhere (25%), typically on the hands and face.[38]

Primary genital HSV-2 infections may be associated with viral meningitis. This complication is manifested as fever, stiff neck, headache, and photophobia with a CSF lymphocytic cellular response and usually a normal glucose level.[173,392] HSV-2 can be isolated from CSF in the early phase of the illness. HSV-2–associated meningitis differs from HSV-1 encephalitis in that it is almost always mild, self-limited, and not associated with neurologic residua.

Other complications of primary HSV genital infection include sacral autonomic nervous dysfunction, which is manifested as poor rectal sphincter tone, constipation, sacral anesthesia, urinary retention, or impotence. Extragenital lesions may be present. These are more frequent in women and occur on the buttocks, groin, thighs, or, less commonly, the fingers or conjunctiva, generally in the second week of disease. In addition, secondary yeast infections in women, and pharyngitis, which usually is associated with fever, malaise, myalgia, headache, tender anterior cervical adenopathy, and a mildly erythematous to diffusely ulcerative or exudative posterior pharyngitis may be seen. Most patients have throat cultures positive for HSV. HSV has been associated uncommonly with acute salpingitis[235] and inguinal lymphadenitis.[388] Transmission to the fetus or neonate is an important and very serious complication of primary or recurrent genital herpes in women of child-bearing age.

Of critical importance is the association of previous HSV infection with an increased incidence of HIV infection.[368] Investigators have considered the possibility that the risk for infection with HIV is enhanced by mucosal ulcers or that the increase in local $CD4^+$ lymphocytes resulting from HSV infection offers a greater number of target cells for HIV attachment and entry. Conversely, individuals with HIV infection reactivate HSV frequently and also have HIV present in mucosal ulcers.[417] A study from Kenya showed that HSV shedding was associated with significantly higher vaginal and cervical HIV shedding, even after controlling for plasma HIV load and $CD4^+$ count.[26] Although all patients with HSV-2 genital infection appear to be at higher risk for acquiring HIV infection, those with recent HSV-2 seroconversion appear to be more susceptible.[312,396] This finding has been confirmed in other populations.[194]

Genital herpes creates significant psychological difficulties for many patients. Whereas many people cope well with the illness and the likelihood of recurrent disease, a syndrome of profound depression, poor self-esteem, complete abstention from sexual activities, and general withdrawal develops in some. This reaction, or "leper syndrome," must be anticipated and discussed in a sensitive and caring manner. Information about the high prevalence of these infections in the population may be helpful, with emphasis placed on the fact that most infected people do not realize that they are infected and shed the virus intermittently, just like those who have had symptoms, as well as effective treatment options.

Other Primary Skin Infections

Mucocutaneous junction areas are common sites of HSV infection, and damaged skin often provides a portal of entry for HSV. Vesicular lesions spread throughout the affected skin and usually crust and resolve in approximately 1 week. The illness accompanying eczema herpeticum can be severe (Fig. 157-6) and even fatal, although in most cases it resolves without specific therapy and leaves no sequelae. Increased use of topical calcineurin inhibitors has raised concern regarding possible immune

FIGURE 157-6 ■ Extensive HSV infection in an infant with atopic eczema (Kaposi varicelliform eruption). (Courtesy Dr. Theodore Rosen, Department of Dermatology, Baylor College of Medicine, Houston.)

suppression and an increase in cases of eczema herpeticum. One study showed the incidence density of herpesvirus skin infections to be similar in infants who received 1 percent pimecrolimus cream and those who received the vehicle without active drug.[288] However, of those children characterized as having eczema herpeticum (more extensive skin involvement), all infants were in the group receiving 1 percent pimecrolimus cream. Further studies are needed to determine the magnitude of risk, if any, of the use of topical calcineurin inhibitors in the development of eczema herpeticum. Current recommendations include discontinuing topical calcineurin inhibitor therapy and beginning appropriate antiviral therapy expeditiously if eczema herpeticum develops.[288]

Widespread herpetic lesions may occur in skin altered by thermal or chemical burns. In this situation, a secondary fever may occur, usually 1 to several weeks after the initial insult. Careful inspection of the burn site or adjacent normal tissue may reveal vesicles (Fig. 157-7) or nonspecific ulcerative lesions. Without therapy, several of these patients have died of disseminated HSV infection.[135] A similar syndrome occurs rarely in children after they have incurred simple skin abrasions (Fig. 157-8). Herpetic recurrences may follow in these cases, but recurrences are localized to the area of skin that was affected initially. HSV can cause severe infection at the site of common diaper rash.[184]

Herpetic whitlow is a painful, erythematous, swollen lesion that occurs on the terminal phalanx, sometimes associated with a damaged cuticle.[34,142,319] The fingers (69%) and thumb (21%) are involved most frequently.[142] Less commonly, the palm may be the site of inoculation and major involvement.[340] The digit is swollen, and the painful white swelling appears to be filled with pus but, when opened for drainage, is found to contain little fluid and no purulent material. The white appearance is caused by the presence of necrotic epithelial cells. Occasionally, the whitlow, which may persist for 7 to 10 days, is accompanied initially by a few vesicles that may give a clue to the etiologic agent of the primary infection. Less commonly, the whitlow is associated with fever, lymphadenopathy, and lymphangitis.[335]

Whitlow is seen in four typical situations. Most commonly, infants with primary herpetic gingivostomatitis autoinoculate their fingers (Fig. 157-9). At times, whitlow is encountered in infants without obvious oral disease, and sometimes it may be caused by adults kissing their children's fingers. In these settings, the viral isolate almost always is HSV-1.[34,142] In sexually active patients, the whitlow more commonly is a manifestation of concurrent genital disease, which should be sought by appropriate history and physical examination.[144] These infections are caused most frequently by HSV-2. In the fourth setting, persons such as dentists, respiratory therapists, nurses, and pediatricians who examine oral cavities or handle

secretion-contaminated material without wearing gloves are at risk for acquiring herpetic whitlow (Fig. 157-10).[129] In addition, health care–associated transmission of HSV to other patients, especially in intensive care settings, may occur if careful attention to use of gloves and other personal protective equipment is not practiced.[3]

Herpetic whitlow frequently is confused with bacterial felon, paronychia, or osteomyelitis of the fingertip. Such confusion may lead to the incorrect intervention of incision and drainage. This procedure is not indicated and is not beneficial in the management of herpetic whitlow, which should be treated with oral acyclovir. Needle aspiration and bacterial and viral cultures provide the diagnosis of whitlow, and initiation of antiviral therapy can be based on clinical signs.

In several sports, cutaneous (especially facial) HSV infection is a hazard, particularly in sports with close physical contact such as wrestling (herpes gladiatorum) and rugby (scrum pox, a name derived from the lineup of rugby players, the "scrum" or "scrummage").[36,76,351,353,431] Frequently, the initial lesions are misdiagnosed as impetigo. HSV infection develops in approximately 3 percent of wrestlers in high school, typically on the head and neck but also on the extremities and trunk and in the eyes.[76]

Infection of the Eye

Ocular herpes occurs as a result of primary infection or reactivation of virus in the trigeminal ganglion. Primary infection may manifest as blepharitis or follicular conjunctivitis. The symptoms often are accompanied by preauricular lymphadenopathy, corneal injection, watering, discharge, itching, lid swelling, and, in a third of cases, malaise and fever. If the infection is restricted to the conjunctivae (which can be accompanied by vesicular herpetic lesions elsewhere on the face or in the nose or mouth), it usually resolves without sequelae or specific features. Herpetic infection of the eye may progress to involve the cornea and progress to keratoconjunctivitis, with far more serious potential consequences. Neonatal HSV infection may also present as keratoconjunctivitis and has been reported after cesarean section delivery over intact chorioamniotic membranes and in twin deliveries.[139,421] For this reason, an ophthalmologic consultant always should examine and evaluate these cases.

Corneal involvement by HSV may be manifested initially as minute vesicles at the corneal margin. Progression of the corneal infection (best seen with the use of topical fluorescein dye) is marked by the appearance of branching lesions (a dendritic pattern) or the less diagnostic irregular (ameboid or geographic) ulcer.[35,101] The child complains of severe photophobia often accompanied by blurred vision, chemosis, and lacrimation. Primary eye infection may include stromal involvement, uveitis, and, rarely, retinitis.[289] Retinitis is manifested as multiple whitish yellow, punctate retinal lesions. Spontaneous healing, which generally requires 2 to 3 weeks, can be speeded by the application of topical antiviral therapy. Corticosteroids are contraindicated. The risk for visual impairment caused by direct viral damage, immunopathologic reactions, or both is enhanced greatly with recurrences. With each bout of infection, the corneal ulcers become more extensive and can result in scarring and impairment of sight. Herpetic infection of the eye recurs in approximately 32 percent of patients who have primary symptomatic infection and occurs more commonly in younger patients.[446] Recurrences may be manifested as blepharitis, follicular conjunctivitis with or without lid lesions, or ulcers and keratitis, which more often are accompanied by ulcerations deeper into the corneal stroma (diskiform or necrotizing keratitis) with resultant extensive scarring, irregular astigmatism, and even corneal perforation.[446] Children with dendritic ulcers have a better prognosis for good vision than do those with geographic or diskiform keratitis.[35]

Rarely, HSV eye infection results in acute retinal necrosis. HSV-2 is the most common cause of acute retinal necrosis identified in childhood. Most affected children have a history of congenital or perinatal herpes infection.[225] Acute retinal necrosis may also be a late sequelae of HSV-1 encephalitis.[100] Many patients have preexisting chorioretinal scars. Reactivation is triggered by periocular trauma or occurs with immunosuppression, such as during treatment with systemic corticosteroids.[398] Symptoms include eye irritation and photophobia.

Very infrequently, an oculoglandular syndrome of conjunctivitis and preauricular adenopathy may be caused by HSV infection.[66]

Infections of the Central Nervous System

HSV is the most common identifiable cause of serious or life-threatening sporadic, endemic encephalitis.[238] It accounts for 2 to 5 percent of all cases of encephalitis in the United States and for as many as 20 percent of all cases with an etiologic diagnosis (60% to 70% of cases of encephalitis have no established cause).[308] With the advent of immunization for measles, mumps, rubella, and varicella, the relative incidence of HSV in cases of encephalitis has increased, although absolute numbers remain stable in children.[210,238,308] The case-fatality rate associated with untreated HSV encephalitis is approximately 70 percent,[443] and survivors generally have severe and permanent neurologic disability. Both HSV-1 and HSV-2 have been implicated in the etiology of CNS

infection by HSV, but typical HSV encephalitis in patients outside the neonatal age range is caused by HSV-1.[1,97,317,339] Spread of HSV-1 to the CNS seems to proceed via either neurogenic pathways or by hematogenous dissemination or perhaps through the cribriform plate from infected nasopharyngeal mucosa during primary infection. Recurrent infection probably results from spread via sensory neurons. HSV-2 meningitis is not associated with brain parenchymal infection; whether the infection is a consequence of hematogenous delivery or spread along neuronal pathways is not known.

Although HSV encephalitis may involve virtually any area of the brain, this infection has a striking tendency to involve the orbital region of the frontal lobes and, with particular frequency, portions of the temporal lobes. The predilection of HSV to involve regions of the brain governing olfaction suggests that a pathogenetic pathway proceeds from the nasal-respiratory mucosa via the olfactory bulbs and along the subsequent tracts into the brain.[187] Other researchers have suggested that reactivated virus travels from the trigeminal ganglia via fifth nerve fibers to the meninges of the anterior and middle fossae.[104,105] HSV brain stem encephalitis also occurs and may be associated with neuro-ophthalmologic findings and cranial nerve deficits.[293] Studies in children involving diagnosis by PCR assay and magnetic resonance imaging (MRI) have defined cases with more diffuse cerebral involvement.[317,341,410]

HSV encephalitis must be differentiated from HSV meningitis, which usually is caused by HSV-2 and is a complication of primary genital or oropharyngeal infection. In HSV meningitis, symptoms and signs of meningitis, including headache, photophobia, and stiff neck, appear before or shortly after genital or oropharyngeal lesions are noted. The signs are similar to those of other acute viral meningitides such as enteroviral meningitis. This syndrome may occur in children as well as adults.[114] HSV-2 meningitis is reported in the absence of lesions[343] and rarely in neonates.[342] Seizures and focal CNS findings generally are absent. Examination of CSF reveals lymphocytosis (with 300 to 2600 white blood cells) and may demonstrate low glucose levels. In cases of HSV meningitis, in contrast to HSV encephalitis, virus is often cultured from CSF,[15,17,97,173] and HSV PCR assay also is diagnostic.[343] Recovery usually is complete without specific therapy, but with the availability of effective antiviral agents, HSV meningitis should be treated with acyclovir. HSV meningitis may reappear with or without obvious genital recurrences. Studies using PCR DNA detection analysis have shown that HSV is the major agent responsible for benign recurrent lymphocytic meningitis, also known as *Mollaret meningitis*.[389] These adult patients had three to nine attacks of recurrent lymphocytic meningitis, with 48 to 1600 cells per liter, normal glucose, and protein concentrations of 41 to 240 mg/dL in CSF. PCR analysis detected HSV-2 and, less commonly, HSV-1. Acute viral meningitis caused by reactivation of HSV-1 also has been described in a preadolescent child.[91]

HSV encephalitis is a highly lethal disease caused by HSV-1 in 93 to 96 percent of cases.[24,270,317,432,436] It may be a result of primary (30%) or recurrent (70%) infection.[270,317] Although no specific data exist, researchers have suggested that HSV encephalitis is more likely to be associated with primary infection in younger persons because new infections occur more commonly in this age group. One report suggests that primary infection is more likely to be associated with fatal encephalitis. Of 113 cases of biopsy-documented HSV encephalitis, 31 percent occurred in patients younger than 20 years and 6 to 10 percent of patients were between 6 months and 10 years of age.[355,356] Unlike most other common forms of viral meningoencephalitis such as enterovirus or arbovirus infection, HSV encephalitis is not seasonal. It is an acute illness characterized by fever, headache, malaise, irritability, and nonspecific symptoms lasting 1 to 7 days, with progression to the signs and symptoms of CNS involvement in 3 to 7 days and, finally, to coma and death (Table 157-1). A biphasic illness consisting of initial improvement followed by worsening may occur. The signs of HSV encephalitis resemble those of other viral encephalitides, with initial fever and altered behavior.[166] Meningeal signs are uncommon findings. No correlation exists between isolation of HSV from sites extrinsic to the CNS (e.g., the oropharynx or genital tract) and the diagnosis of HSV encephalitis.[270,433] Thus, the presence of oral or genital lesions is of no help in the establishing or excluding the diagnosis of HSV encephalitis. Nonetheless, if a patient has HSV encephalitis, identical viruses have been isolated from the brain and oral secretions.[439]

The CSF generally reveals pleocytosis, with as many as 2000 white blood cells/mm^3 but usually (80% of the time) more than 50 white blood cells/mm^3. In 90 percent of cases, more than 60 percent of the cells are lymphocytes. Early in the course of infection, neutrophils may predominate. In 75 to 85 percent of cases, red blood cells, reflecting the hemorrhagic necrosis, are seen in the CSF. Between 5 and 25 percent of patients have

hypoglycorrhachia, and 80 to 88 percent have elevated protein levels in CSF (median, 80 mg/dL), which rise to striking levels as the disease progresses. Two to 3 percent of patients with early HSV encephalitis have normal CSF.[211,270] Repeat analysis of CSF usually reveals abnormalities consistent with encephalitis. HSV almost never is cultured from lumbar CSF in patients outside the neonatal age range and rarely has been grown from ventricular fluid.[136] Thus, whereas CSF examination is helpful, it is not at all diagnostic of HSV encephalitis. When the CSF of patients with HSV encephalitis is compared with that of patients undergoing biopsy for suspected HSV but with another resultant diagnosis, no differentiating characteristics of CSF are found that could allow one to predict HSV infection accurately. HSV DNA can be detected by the use of PCR assay of the CSF of patients who have HSV encephalitis.*

Neurodiagnostic tests have been of limited assistance. Probably one of the most useful is the electroencephalogram (EEG) (Fig. 157-11).[50] A "typical" pattern of unilateral or bilateral (poor prognosis) periodic focal spikes against a background of slow (flattened) activity (paroxysmal lateral epileptiform discharges [PLEDs]) has been associated with HSV encephalitis. These findings are suggestive but not pathognomonic. Other findings include large-amplitude, irregular slow activity, sharp waves, and variable spikes. In 80 to 90 percent of patients, the EEG is not only abnormal but also localizing. In many cases in the pediatric and adult age groups, the EEG may be one of the earliest localizing laboratory tests.[112,150,209] Less commonly, the results of a radionuclide or computed tomographic (CT) scan are abnormal and localizing (50% to 60% of cases).[193,236] CT results may be characteristic late in the illness and consist of low-density, contrast-enhanced lesions in the temporal area, mass effect, edema, and hemorrhage (Fig. 157-12); early in the illness, when establishing the diagnosis is critical, CT results more often are unremarkable.[150,209,264] Abnormal CT results are a poor prognostic factor.[264] MRI findings are more likely to be abnormal at initial evaluation for HSV encephalitis because of its high sensitivity to changes in brain water content[348] (Fig. 157-13), and MRI is more sensitive than is CT for detection of HSV encephalitis.[109,302] Findings include hyperintensity of the temporal and brain stem areas on T2-weighted MR images, and imaging results may be normal if performed in the early stages of the disease.[4]

Focal abnormalities in HSV encephalitis are significantly more likely to be observed on EEG, CT, MRI, or radionuclide brain scan than in other illnesses confused with it. All these findings are biased by the current concept of HSV encephalitis as a focal encephalitis, with very few biopsy data available on the etiology of nonfocal encephalitis. Whether a significant number of cases of HSV encephalitis are milder and nonfocal is unknown, because few of them ever come to brain biopsy or even careful retrospective serologic diagnosis. Studies using MRI and PCR technology have identified cases with multifocal brain involvement.[236,341]

Clinical and laboratory evaluations of patients with suspected HSV encephalitis are valuable only for increasing the index of suspicion, not for confirming the diagnosis. In one series of 24 children with HSV encephalitis diagnosed by PCR assay and compared with 38 children in whom HSV encephalitis was excluded by PCR, no significant differences were found in clinical manifestations at onset or in CSF cell counts, protein, or glucose.[181] However, more children with HSV encephalitis had localizing findings detected by CT (75% vs. 31%), whereas 36 percent of those without HSV encephalitis had EEG abnormalities as opposed to no EEG abnormalities detected in those with HSV encephalitis.

The differential diagnosis of HSV encephalitis is large (Table 157-2). Especially in the pediatric age range, the ability to discriminate HSV encephalitis from other etiologic agents mimicking it is poor (50% in the national collaborative series in 71 patients younger than 20 years and 42% in a smaller series of 12 patients younger than 12 years).[209] Confirmation of the specific diagnosis of HSV encephalitis remains essential, both to provide optimal aggressive therapy for that condition and, of equal importance, to achieve a diagnosis for the 50 to 60 percent of patients without HSV infection, roughly 16 percent of whom would benefit from other specific therapies.[112,209,264,433] In most cases, the diagnosis can be established by PCR analysis of CSF.* Large studies show PCR analysis to be 98 percent sensitive and 94 percent specific when compared with brain biopsy.[222] Some of the 6 percent "false-positive" results probably were due to poor handling of the biopsy tissue for culture. PCR analysis may yield positive results by 1 day after the onset of symptoms.[153] However, a negative PCR result obtained soon after the onset of symptoms does not exclude the diagnosis of HSV encephalitis. In two small series of patients, repeat testing of CSF 4 to 7 days after an initial negative HSV PCR assay showed positive PCR results.[427] HSV DNA persists in most specimens for a week or more, even after antiviral therapy.[399,432] PCR primers must be chosen to detect HSV-2, as well as HSV-1, because 4 to 6 percent of HSV encephalitis cases may be caused by HSV-2.[24]

If PCR results are negative in a patient who has symptoms and signs of HSV encephalitis, repeat CSF HSV PCR analysis should be performed, and if still negative, and the patient's condition is progressively worsening, brain biopsy may be contemplated. The risk associated with brain biopsy is low. In the national collaborative study of 432 biopsies, six complications occurred (hemorrhage in three patients and poorly controlled brain edema in three, for a 1.4% complication rate).[436] Roughly 2 to 3 percent of brain biopsies yielded false-negative results, usually because of biopsy of the wrong site.[436] Decision analysis suggests that performing a biopsy is especially critical in a patient with low CSF glucose levels.[337]

Quantitative PCR analysis may have value as a prognostic tool and as a method of assessing the response to antiviral therapy in patients with HSV encephalitis.[14,432] In 16 patients, those with high copy numbers of HSV DNA in CSF tended to have abnormal CT scans, be older, and exhibit more severe sequelae. HSV DNA levels were found to decrease during acyclovir therapy in seven patients; the exception was a patient whose copy numbers increased and who subsequently had a fatal infection.

A less acute form of HSV encephalitis in immunocompromised patients has been reported. Also less commonly, HSV has been implicated in brain stem encephalitis.[124]

Relapse occurs in approximately 5 percent of treated patients.[209] Choreoathetosis may be an initial sign of relapse.[216,422] Reports of a postherpetic encephalomyelitis caused by a probable autoimmune or demyelinating etiologic factor have appeared[2,206]; moreover, virus-positive recurrence of HSV encephalitis has been described months after patients have undergone apparently successful therapy.[113] These consequences can be differentiated and documented only by PCR analysis or, if necessary, brain biopsy and appropriate tissue histologic examination and culture.

Infection of the Gastrointestinal Tract in Normal Hosts

Whereas infection of visceral organs is well recognized in immunocompromised hosts, case reports of such infection in apparently healthy persons are less common.

Nonetheless, HSV esophagitis has been described in patients, including several children who were 11 months to 17 years of age.* Esophagitis has recently been reported as complication of wrestling.[196] HSV-1 is the usual pathogen, and the syndrome is associated with primary infection.[117] Initial symptoms include fever, severe odynophagia, retrosternal and subxiphoid pain, and an inability to eat. Oral lesions may be present, but skin lesions generally are absent. Esophagoscopy reveals ulcerations and fibrinous and, at times, hemorrhagic exudate. Distal involvement may be more extensive than the proximal esophageal findings suggest. Double-contrast esophagography may be diagnostic, although endoscopy and biopsy usually are necessary for establishing a definitive diagnosis. Symptoms generally remit in 5 to 7 days after the administration of acyclovir and nonspecific therapy such as antacids, histamine-2 blockers, and hydration.[18,64,263] Perforation of the esophagus is a rare complication.

HSV infection can manifest as an anorectal infection in males who have sex with males.[147,304] In most series of HSV proctitis, cases are in younger adolescent males involved in passive anal intercourse. This syndrome occasionally affects women practicing passive anal intercourse. Initial symptoms include severe anorectal pain, discharge, tenesmus, hematochezia, and, in particular, fever, difficulty urinating, sacral paresthesias, constipation, and (in 50% to 70% of patients) ulcers or vesicles in the perianal or distal rectal area.[147] The duration of symptoms is 2 to 3 weeks. Primary HSV infection accounts for proctitis in this group in 25 to 30 percent of cases. Syphilis and infection with *Giardia lamblia*, *Entamoeba histolytica*, *Campylobacter fetus*, *Shigella* spp., other enteric bacteria, and *Neisseria gonorrhoeae* also must be considered in the differential diagnosis of this entity. Appropriate cultures and histologic analysis are crucial for establishing a specific diagnosis.

HSV is a rare cause of hepatitis and represents a broad spectrum of disease from mild elevation of aminotransferases to fulminant liver failure and death. HSV-1 and HSV-2 should always be considered in the differential diagnosis of acute liver failure.[407] HSV hepatitis occurs in all ages, from neonate to adult, and occurs in both immune-competent and special hosts.[28,254,260] In one review of the literature describing 35 patients who had HSV-associated hepatitis, 14 percent had no underlying condition. The remainder had various immunocompromising conditions such as transplantation, corticosteroid administration, pregnancy, burns, primary immunodeficiency, or cancer. These patients tended to have fulminant hepatic necrosis, extremely elevated serum aminotransferase levels, disseminated intravascular coagulation, and a mortality rate of 86 percent.[82] In a prospective study of healthy young adults with genital herpes (primary or recurrent), 14 percent had mild elevations in liver enzyme tests.

Recurrent Infections

HSV-1 and HSV-2 have the characteristic capacity of herpesviruses to establish latency and undergo episodes of reactivation despite the presence of an apparently adequate immune response. Persistence is facilitated because latent infection of neurons occurs in an immunologically "privileged" site. Reactivation of HSV infection with viral shedding generally causes no lesions. HSV can be recovered from the pharynx and genital sites of asymptomatic persons. It has been found in the tears of persons with a history of recurrent ophthalmic disease,

*References 18, 30, 64, 138, 263, 285.

even in the absence of eye lesions or symptoms. All HSV-2–seropositive women from whom samples of vaginal secretions were obtained for more than 100 days had documented asymptomatic viral shedding, and shedding occurred on 1 percent of the days on which cultures were performed.[420]

Patterns of HSV reactivation include asymptomatic reactivation after silent primary infection, asymptomatic reactivation after symptomatic primary infection, and symptomatic recurrence after either silent or symptomatic primary infection. The risk for having symptomatic recurrences may be higher in individuals who have symptomatic primary infections. When reactivation causes disease, the clinical manifestations of recurrent HSV infection depend on the area involved. Most HSV recurrences are milder than the primary illness, although patients may have symptomatic recurrences without having had clinically apparent primary disease. Recurrent infection in a normal host also may be more severe than is the primary infection. This pattern is particularly evident in HSV infection of the eye, in which recurrent illness is associated with deep stromal damage and scarring.[299,454] This enhanced severity may be related to a greater extent to a more exuberant immune response than to viral damage. HSV encephalitis, which may be a manifestation of viral reactivation, is devastating.[270,317]

The most common manifestation of recurrent HSV infection is herpes labialis ("cold sores," "fever blisters"). Recurrences are observed in 25 to 50 percent of persons who have had symptomatic primary HSV-1 oral infection but in only 24 percent of those who had primary HSV-2 oral infection. The mean rate of recurrence after symptomatic primary HSV-1 infection in adults is approximately 0.1 per month. These recurrences often are associated with a variety of febrile illnesses, local trauma, sun exposure, or menstruation.[25,363,366] Whether acquisition of HSV-1 in childhood is less likely to be associated with recurrent herpes labialis is not known.

Most persons with herpes labialis experience a prodrome (pain, burning, tingling, or itching) at the site that lasts a few hours to several days. Subsequently, an orderly progression ensues from papules (lasting 12 to 36 hours) to vesicles (usually gone by 48 hours) and finally to ulcers and crusting (lasting 2 to 4 days) (Fig. 157-14). The typical lesion measures 35 to 80 mm. The majority of outbreaks are healed by 5 to 10 days (mean, 200 hours). Most pain occurs during the vesicular stage. Virus is isolated readily from vesicles (80% to 90% of the time) and less commonly from ulcers and crusts (34% of the time). Maximal virus titers (10^7 to 10^8) in lesions are detected in the first 1 or 2 days, and virus generally is not isolated after 120 hours.[25,366] Virus is detected in the saliva and on the hands of persons with herpes labialis.

Recurrences tend to affect the same location or closely related areas. In general, they occur on the lips, mucocutaneous junction, or other parts of the face. Recurrent lesions found inside the mouths of normal hosts rarely are caused by HSV and more likely are aphthous lesions. When HSV recurrences are within the mouth, they tend to be on tissue adjacent to bone, such as the gums or palate, and not on the lips or buccal mucosa.[361] A differential diagnosis of the condition also includes pemphigus, lichen planus, ulcers caused by cyclic neutropenia, and ulcers associated with celiac disease, ulcerative colitis, Crohn disease, pernicious anemia, and Behçet syndrome.

FIGURE 157-14 ■ Recurrent herpes labialis (cold sore) in an adolescent.

Recurrent genital herpes is the second most common manifestation of HSV. Studies have elucidated several factors that increase the risk for recurrent genital disease after symptomatic primary genital infection. Recurrence rates are much higher after primary HSV-2 (90%) than after primary HSV-1 (25% to 55%) infection.[220,309] The mean rate of recurrence is 0.02 to 0.1 per month after primary genital HSV-1 infection and 0.3 per month after primary HSV-2 genital infection.[220,309] Recurrences are seen more commonly in men than in women and after a recurrent lesion than after a first attack.[309]

Only 5 to 12 percent of persons with recurrent genital herpes have constitutional symptoms. Local symptoms include pain (average, 4 to 6 days), itching, dysuria (10% to 30%), adenopathy (20% to 30%), and lesions (average, 50 to 60 mm) lasting 4 to 5 days until crusting, with healing taking place by 9 to 11 days (range, 4 to 29 days) (see Fig. 157-3). Symptoms in females tend to be more severe than those in males. Virus is shed for an average of 3 to 4 days (but in some cases as long as 20 days). Virus generally is shed with titers of 10^2 to 10^4 per lesion. Vesicles are seen in dry areas, but in wet areas the vesicles rapidly break down into ulcers. Symptoms generally are milder and of shorter duration than those in primary genital disease.[53] New crops of lesions commonly occur during the course of recurrence. The severity of

recurrence is quite variable; in some cases, several discrete recurrences blend into a single, prolonged recurrence, and in rare cases, patients have almost continuous recurrences.[154] In one study of patients who were HSV-2 seropositive with no history of genital herpes, 62 percent had recognized herpetic lesions at later evaluation.[420] Recurrences in the previously asymptomatic group were shorter (3 vs. 5 days) and less frequent (3.0 vs. 8.2 per year) when the pattern of recurrence in this cohort was compared with that of subjects with a known history of genital herpes.

With endonuclease restriction analysis, researchers have clear evidence that, whereas most recurrences represent endogenous reactivation of the same latent virus, reinfection with a new homologous virus (i.e., HSV-2 and new HSV-2), as well as heterologous virus (i.e., HSV-2 and then HSV-1 or vice versa), is possible.[62] How common this occurrence is remains to be ascertained and must depend to some degree on the sexual activity and number of partners of the persons studied.[346]

Other cutaneous recurrences may develop at each anatomic site of primary infection. HSV infection may recur on the face or trunk in a typical dermatome distribution, such as that associated with VZV. Indeed, frequent repeated attacks of zosteriform-like lesions on any part of the body in a normal host suggest HSV and not VZV infection.

Erythema Multiforme

Erythema multiforme is thought to be an immune-mediated, "allergic" response to recurrent HSV infection.[133,178,261,280,429] It has been associated with the presence of human leukocyte DQw3 antigen.[192] In several series, approximately 15 to nearly 100 percent of patients who have erythema multiforme, especially those with recurrent erythema multiforme, gave a history of recurrent HSV infection before the skin eruption, which may be macular or urticarial.[178] In one series, 5 of 80 patients who had recurrent oral HSV infection experienced a rash (presumably erythema multiforme) that manifested 8 to 14 days after the onset of a cold sore.[366] Studies in adults and children have documented HSV antigen-antibody immune complexes and HSV DNA (detected by PCR analysis and in situ hybridization) in the skin of patients who had erythema multiforme after having HSV infection.[47,48,280] In a series of 20 children with erythema multiforme (10 who had antecedent herpes), 16 were documented to have HSV DNA at the site of the rash.[429] The mechanism of transport of viral DNA fragments is not clearly understood. Recent studies suggest that $CD34^+$ cells play a role in transport of HSV DNA fragments to lesional skin.[279]

The skin manifestations may last 14 to 21 days, and therapy generally is directed toward the allergic and not the viral component of the illness. Suppression of HSV recurrences prevents the associated episodes of erythema multiforme. Indeed, suppressive treatment of erythema multiforme with acyclovir, even in the absence of recurrent HSV infection, completely suppresses clinical manifestations.[347,387] In one series, the syndrome developed in 12 children at a mean age of 8 years within 4 days after the appearance of herpes labialis lesions and symptoms lasted for an average of 10 days; 9 children had recurrent erythema multiforme, with an average of 2.6 episodes per year.[429] Detection of HSV by PCR assay of skin biopsy tissue was described in all cases. None of three children given acyclovir suppressive therapy had recurrences during treatment for at least 6 months, but erythema multiforme with recurrent HSV developed in one child when use of the drug was discontinued, thus supporting a causative role of HSV in the syndrome.

HSV Infection in Immunocompromised Hosts

As the practice of pediatrics continues to include more patients with severe acquired immunodeficiency states brought about by increasingly intensive therapy for malignancies and primary immune deficiency disorders, expanding application of bone marrow and organ transplantation, and HIV infection, the prevalence of severe HSV infection in immunocompromised hosts is increasing. Table 157-3 lists conditions associated with unusually severe HSV infections. Aside from several cases of HSV encephalitis in patients with agammaglobulinemia

TABLE 157-3 **Conditions Contributing to Unusually Severe HSV Infections**

Neonatal period

Tuberculosis
Severe bacterial infection
Haemophilus influenzae meningitis
Sarcoidosis

(who also had concomitant infections with enterovirus),[242] common links in these varied groups are either skin abnormalities (eczema, burns) or immunologic defects, primarily in the cell-mediated components of the immune system.* The critical defects have not been defined and may involve one or a combination of inadequate functions (e.g., of $CD4^+$ T cells, $CD8^+$ T cells, natural killer cells, macrophage antigen processing, or other factors).

The incidence of severe HSV infection in children with diseases that predispose them to these complications (see Table 157-3) is defined poorly but, in limited series, was similar to that seen in adults.[137,145,306,317] Most infections are caused by reactivation, as would be expected given the relative frequency of primary and recurrent infections.

In series of pediatric or adult patients who have received renal, bone marrow, or cardiac transplants, 70 to 90 percent of seropositive persons excreted HSV, usually from the oropharynx and generally at the time of peak immunosuppression (in the first month after transplantation).[271] HSV disease usually occurs within 2 to 3 weeks of solid organ or hematopoietic transplantation in patients who do not receive antiviral prophylaxis.[145] Of 68 children who underwent renal transplantation, a herpesvirus was isolated in 43 percent, with 28 percent of the isolates being HSV.[397] HSV in cardiac transplant cases causes symptomatic illness in 45 to 85 percent of seropositive patients, depending on the intensity of immunosuppression. HSV was the virus most commonly isolated in children who underwent bone marrow transplantation (23%).[424] HSV has been suggested to be one of the etiologic agents of the interstitial pneumonitis that develops after bone marrow transplantation.[274,307] In children with leukemia, HSV infection occurs more commonly in those with myelocytic leukemia than in those with lymphocytic leukemia and the risk for the development of infection increases with neutropenia and chemotherapy. HSV infection was the most common serious viral infection in children with leukemia. Whereas most infections occurred during periods of remission, on a per-day basis, the risk for development of infection was seven times higher during induction.[448]

In Africa, patients suffering from underlying malnutrition and concomitant measles infection may contract fatal disseminated HSV infection; such events rarely occur in industrialized nations.[33,201,391]

In children with HIV infection, HSV causing chronic mucocutaneous ulcers (persisting for more than 1 month), bronchitis, pneumonitis, and esophagitis is an AIDS-defining condition.[77] Chronic ulcerative HSV lesions often develop in children with HIV infection.[333] Chronic HSV mucocutaneous disease or widespread organ involvement was reported as the AIDS-defining condition in 7 of 789 (0.9%) HIV-infected children in one analysis.[401] In another series of children with AIDS, 5 to 29 percent contracted HSV opportunistic infection.[137] Many of these children have perianal ulcers from which HSV-1 is isolated. In HIV-infected patients, dissemination is a rare occurrence.[19] Multiple recurrences of infection are common occurrences as the immunodeficiency worsens. In patients with AIDS, HSV can cause a typical[159,408] or more indolent encephalitis. HSV usually does not result in mortality in HIV-infected patients, but it causes significant morbidity.[203] HSV genital ulcer disease increases the risk for acquisition of HIV.[175] Studies show that suppression of clinical and subclinical reactivation of HSV is associated with a decrease in HIV viral load.[338] In one recent study, daily acyclovir therapy did not reduce the risk for transmission of HIV-1, despite a reduction in plasma HIV-1 RNA and a 73% reduction in the occurrence of genital ulcers due to HSV-2, suggesting that a more substantial reduction in plasma HIV-1 RNA is necessary to reduce transmission.[74]

Several major syndromes are attributable to HSV in immunocompromised patients, with some overlap and occasionally progression from one to another. The first and most common manifestation is a local, chronic, often extensive cutaneous or mucocutaneous infection. The second form is infection involving a single organ (e.g., esophagitis or pneumonitis). The most serious illness is characterized by more widespread dissemination involving distant areas of the skin or visceral organs (e.g., the lungs, liver, adrenal glands) and the CNS. Although data are limited, disseminated disease probably most often represents primary infection except in the most severely immunocompromised patients. More localized syndromes may be a manifestation of either primary infection or recurrent illness.

The typical localized HSV infection begins in the mouth or about the lips, often appearing innocuously as recurrence of ordinary herpes labialis. Over the course of several days, the papules and vesicles progress to bullae, frequently with hemorrhagic fluid. The bullae or vesicles evolve into huge, chronic, bloody, coalescing, ulcerated, oozing lesions eroding into subcutaneous tissue and occasionally destroying underlying structures. The tissue is malodorous, and the lesions are painful (Fig. 157-15). The lip and palate are the sites most commonly affected. Oral lesions account for approximately 60 percent of

HSV infections in children undergoing transplantation.[397] A similar syndrome, usually caused by HSV-2 infection, may be seen in the perianal or vaginal area and is one of the characteristic syndromes that occur in males who have sex with HIV-infected males (Fig. 157-16). If untreated, the lesions may lead to death because of local destruction and hemorrhage, or they may regress as the immune status of the host improves or as antiviral chemotherapy is administered. A syndrome of herpetic geometric glossitis has been reported in HIV-infected patients.[152] Affected patients have a tender tongue accompanied by dorsal longitudinal crossed and branching fissures.

Extensive HSV skin infections may occur in patients with burns, eczema, pemphigus, or abrasions, often with conversion of second-degree tissue damage to third-degree damage (see Figs. 157-6 and 157-7). Of 179 children with eczema, herpes skin infections developed in 10, 7 of whom required hospitalization.[103] Although rare, local infection may progress to dissemination in some cases, possibly as a result of the more severe immunodeficiency occurring with several of these conditions. The widespread necrotizing lesions are known commonly as *Kaposi varicelliform eruption* or *eczema herpeticum* (see Fig. 157-6). The predisposition to severe HSV-1 infection in children with atopic eczema appears to be due to the cutaneous abnormalities because these children have T-cell responses to HSV, as well as high HSV IgG antibody titers.[148] Studies have looked at the role of the cathelicidin family of antimicrobial peptides in protecting children with atopic dermatitis against disseminated skin infection with HSV. Variable skin expression of cathelicidin peptide LL-37 may explain why eczema herpeticum develops in some children with atopic dermatitis and others appear to be at lower risk.[148,176] One study evaluating phenotypic risks for eczema herpeticum demonstrated that children with severe atopy and greater T-helper type 2 (Th2) polarity (as demonstrated by an increase in Th2 chemokines) were at increased risk for HSV and *Staphylococcus aureus* skin infections.[32]

Herpes skin lesions must be differentiated from bacterial infections caused by gram-positive or gram-negative organisms, chronic fungal infections (as seen with *Mucor* or *Blastomyces*), other viral infections (vaccinia, varicella), mycobacterial infection, and various noninfectious lesions such as pyoderma gangrenosum, chemotherapy-induced ulcers, or Sweet syndrome.

HSV esophagitis rarely has been reported in normal children,[30,64,196] but it is a relatively common finding in immunocompromised patients. Pathologic studies have suggested that approximately 25 percent of cases of autopsy-proven esophagitis (1% to 6% of all autopsies) are secondary to HSV infection (14 of 55 cases).[273] Underlying conditions included burns, aplastic anemia, malignancies, transplantation, a variety of other serious medical problems, and postoperative trauma induced by nasogastric tubes.[64,248,273] Twenty to 50 percent of these patients have HSV involvement elsewhere (the lungs, trachea, and, less commonly, the skin). The esophagitis may be asymptomatic or associated with dysphagia, odynophagia, epigastric discomfort, and retrosternal pain. Characteristic findings in the esophagus are ulcers with raised granular margins. The ulcers often are covered with fibrinous exudate and, in advanced cases, are confluent, with progression to complete mucosal loss in large segments of the esophagus. Typically, visceral herpes infection is not suspected before the patient's death, but, uncommonly, involvement of adjacent gastric tissue can be documented. Diagnostic evaluation should include a barium swallow, which may demonstrate edema, nodules, and ulceration of the esophagus; however, barium studies cannot differentiate HSV from other etiologic agents of esophagitis. Esophagoscopy accompanied by biopsy and viral culture is diagnostic and helps exclude other common causes of this syndrome, including *Candida*, CMV, and possibly other fungi and bacteria or chemotherapy-induced changes.[63,64,273] Although the oral cavity, esophagus, and rectum are the usual sites of HSV infection in the gastrointestinal tract of immunocompromised patients, HSV-2 colitis has been reported in a young child after combined liver and small bowel transplantation.[108]

HSV pneumonia is an unusual condition, but lung involvement has been described in neonates[39] and immunocompromised hosts. This diagnosis frequently is made post mortem almost exclusively in immunocompromised patients. In one series of 1000 consecutive autopsies,[272] HSV pneumonia was identified in 10 cases. HSV

pulmonary infection occurred in 3 percent of children who had undergone renal transplantation.[397] In most adult cases, the process is a result of endogenous viral mucocutaneous reactivation and involvement of lung tissue by contiguous spread, which causes focal pneumonia (60% of the time), or involvement by hematogenous spread from an oral or genital site, which results in diffuse pneumonitis.[307] Although the largest series consisted primarily of adult patients, three of the patients were aged 7 years or younger (with Down syndrome and congestive heart failure, rhabdomyosarcoma, and pneumococcal pneumonia and a seizure disorder).[179] Patients had cough, dyspnea, fever, and hypoxia; and 50 percent had rales. Most had other concomitant pulmonary infections with bacteria, *Candida*, *Aspergillus*, and CMV. HSV pneumonia cannot be diagnosed by the association of upper airway cultures and radiographic abnormalities. It must rest on an aggressive approach involving culture and histopathologic examination of involved lung tissue obtained by either biopsy or bronchoscopy.

HSV meningoencephalitis is not a common occurrence in immunocompromised patients. It may occur as a component of widely disseminated disease, or it may be a localized condition. Several cases have been reported in patients who had agammaglobulinemia in association with concomitant enteroviral infection of the brain.[242] The meningoencephalitis may be fulminant, such as occurs in a normal host. An interesting case that followed an atypical subacute course accompanied by bilateral brain involvement has been reported in an anergic patient who had Hodgkin disease. HSV encephalitis may also involve the brain stem.[243] Although HSV does not appear to have a predilection for CNS infection in immunocompromised hosts, patients with AIDS are an exception and may have ascending myelitis, acute transverse myelitis, and encephalitis.[137,140,159,408]

Hepatitis caused by HSV has been reported most commonly after solid organ or bone marrow transplantation[185,217] and during pregnancy.[202] Signs include fever, abdominal pain, and elevated liver enzyme levels. Hepatitis usually occurs during the first 3 weeks after transplantation, unless prophylactic acyclovir is given. The mortality rate is very high (67% to 100%). In at least one case, orthotopic liver transplantation resulted in survival.[352] HSV is reported as the most frequently identified viral etiology of hepatitis on one series of patients with systemic lupus erythematosus.[306]

The most severe form of HSV in an immunocompromised host is widely disseminated disease that can involve the liver, adrenals, lungs, spleen, kidney, and often the brain. In studies from South Africa and Kenya,[33,201,391] measles and severe malnutrition were frequent cofactors in children who had widely disseminated HSV infection. These illnesses represented fatal primary infections. Similar syndromes have been described; they and other underlying conditions are listed in Table 157-3. Dissemination has been reported coincident with *Bordetella pertussis*, *Haemophilus influenzae* meningitis,[183] and other bacterial infections.[33] Disseminated HSV infection occurred in 10 percent and 25 percent of children who had HSV infection and underwent bone marrow and renal transplantation, respectively.[271,424]

Disseminated HSV infection initially usually manifests as initial fever and skin or mucocutaneous involvement in 80 percent of cases, but instead of healing as expected, the infection disseminates. The cutaneous dissemination may involve a widespread vesicular eruption that looks much like varicella, or it may involve more local, large hemorrhagic vesicles and bullae. Involvement of the major target organs, as noted previously, gives rise to syndromes of hepatitis, pneumonia, shock, bleeding, disseminated intravascular coagulopathy, seizures, coma, renal failure, hypothermia, and death in days to weeks. Laboratory examination may reveal leukopenia, thrombocytopenia, elevated liver function test values, hyponatremia, azotemia, pneumonitis, hypoglycemia, CSF pleocytosis, abnormal EEG results, and electrocardiographic abnormalities. Death occurs commonly in this syndrome (90%), even after the institution of antiviral chemotherapy. Because the liver frequently is involved and biopsy may be precluded by the tenuous condition of the patient, HSV infection should be considered in all high-risk groups (see Table 157-3) with fulminant hepatitis.

Fetus and Newborn

HSV may infect the fetus before delivery (congenital or in utero infection), infect the newborn during delivery (perinatal or natal infection), or infect the infant after birth (postnatal infection).

The clinical spectrum in infants with congenital HSV infection is different from that observed in infants with natal or postnatal disease. The classic triad of cutaneous findings, CNS disease, and ophthalmologic disease is seen in approximately one third of neonates with congenital HSV.[250] The most prominent and most common features of congenital infection are vesicular rash, bullae, or cutaneous scars present at birth or within a few days of birth. In some cases, the extent and severity of these lesions may result in an initial diagnosis of epidermolysis bullosa. At least one case report of limb hypoplasia, similar to congenital varicella syndrome, has been shown to be caused by HSV-2.[185a] Two thirds of infants demonstrate extensive involvement of the CNS at birth, either clinically or from autopsy findings: diffuse brain damage, microcephaly, or intracranial calcifications. In some infants, eye findings, including chorioretinitis, microphthalmos, retinal scars and retinal dysplasia, and cataracts, have been noted.

The three general patterns of natal or postnatal neonatal HSV infection are categorized by the extent of disease: (1) disseminated infection with or without CNS involvement, present in 25 percent of cases; (2) infection localized to the CNS in 30 percent of cases; and (3) infection localized to the skin, eye, or mouth in 45 percent of cases.

Infants with natal or postnatal HSV infection commonly have a clinical picture resembling that of bacterial sepsis: alterations in temperature, lethargy, respiratory distress, anorexia or vomiting, and cyanosis. In febrile neonates presenting to an acute care treatment center, HSV infection should be considered in the differential diagnosis of neonatal fever, especially in the presence of

mononuclear CSF pleocytosis, hypothermia, or sepsis-like syndrome.[69-71] If skin involvement is present, then skin vesicles or mucous membrane ulcers may be apparent. If the conjunctivae or cornea is involved, then nonexudative conjunctivitis, tearing, and pain will be present. If the CNS is involved, then seizures may occur.[421] The frequency of disseminated disease has decreased after a high of 51 percent reported in the years 1973 to 1981; this decrease probably represents earlier diagnosis and treatment of localized infection before dissemination occurs.[436a] The disseminated form of infection in the earlier years of recognition presented in infants between 9 and 11 days of age and usually involved the liver, where it caused fulminant hepatitis with disseminated intravascular coagulation, and the adrenal glands, and it most closely resembled the picture of bacterial sepsis.[407] Current reports show disseminated neonatal HSV may present as early as the first week of life, without cutaneous or localizing signs, similar to bacterial sepsis, and confirm that HSV remains an important cause of neonatal morbidity and mortality. A disseminated infection can affect multiple organs, including the brain, larynx, trachea, lungs, esophagus, stomach, lower gastrointestinal tract, spleen, kidneys, pancreas, and heart. Pneumonia occurs in 37 percent of infants. Markedly elevated aminotransferase levels, direct hyperbilirubinemia, coagulopathy, and thrombocytopenia are common findings late in the disease process. Sixty to 75 percent of infants with disseminated disease have hematogenously acquired CNS involvement and meningoencephalitis, as manifested by irritability, a bulging fontanelle, localized or generalized seizures, flaccid or spastic paralysis, opisthotonos, decerebrate rigidity, or coma. Importantly, 39 percent of infants with disseminated disease do not have skin vesicles or eye lesions at initial evaluation and vesicles do not develop during the acute HSV disease; only 56 percent initially have fever, and many are hypothermic on presentation.

CNS disease from retrograde axonal transmission of virus presents later than does disseminated disease, usually when the infant is 11 to 17 days old but occasionally when the infant is as old as 4 to 6 weeks of age. Typically, these infants have focal seizures that subsequently generalize. Examination of CSF demonstrates mononuclear pleocytosis with a predominance of lymphocytes, a moderately low glucose concentration, and elevated protein levels. A normal cell count, glucose, and protein concentration, however, may be found on the initial lumbar puncture, if performed early in the disease process. An elevated red blood cell count secondary to hemorrhagic brain involvement may be present but by itself is an unreliable sign. Fever is present at initial evaluation in only 44 percent of infants with HSV encephalitis, and 32 percent of infants do not have skin vesicles either initially or during the course of their illness. Neonatal HSV encephalitis can be multifocal or limited to only the temporal lobes, brain stem, or cerebellum; and watershed distribution ischemia may be seen in some cases.[293,410]

Localized skin, eye, or mouth disease usually presents within the infant's first 7 to 10 days of life. Approximately 83 percent of these neonates have skin lesions: usually single vesicles, occasionally vesicle clusters, and rarely a zoster-like rash. As many as 46 to 80 percent of neonates with skin lesions have 1 to 12 recurrences during the first 6 to 12 months of life. Thirteen to 25 percent of infants have eye involvement; disease is limited to only the eye in one third of these cases, but the risk for disseminated disease is significant.[421] Common manifestations include eye pain and eyelid swelling, fussiness, tearing, nonexudative conjunctivitis, keratitis, and chorioretinitis. As many as 83 percent of infants are afebrile initially. One third of all infants have evidence of herpetic mouth lesions.

DIAGNOSIS

Clinical findings may suggest a probable diagnosis of HSV infection, but obtaining a definitive laboratory diagnosis is necessary or useful in many circumstances and should always be sought in neonates and patients with severe disease.[16,72] Accurate laboratory diagnosis requires giving attention to obtaining the correct specimens necessary for identifying the etiology of the clinical syndrome. Appropriate interpretation of the laboratory results is the second critical factor. Evaluation of mucocutaneous lesions in high-risk patients guides the use of antiviral therapy if the lesion is herpetic. However, because HSV often is shed in immunosuppressed and otherwise healthy individuals, finding HSV in oropharyngeal secretions does not mean that the clinical condition is caused by HSV. In general, the virus must be isolated from the relevant tissue for confirmation of the diagnosis. The test selected also is important (e.g., HSV is rarely found in CSF cultures of patients outside the neonatal age group with HSV encephalitis but often is present in aseptic meningitis caused by HSV). Detection of HSV DNA in CSF by PCR assay or by brain biopsy is indicated to prove the diagnosis and exclude other treatable causes of encephalitis. Laboratory diagnosis also is valuable when HSV infections are not life threatening.[72] For example, establishing that a genital lesion is caused by HSV-1 or HSV-2 facilitates decisions about antiviral therapy and allows initiation of appropriate counseling regarding the risk for recurrences and measures that may reduce transmission of HSV to contacts and during pregnancy to the neonate.

Viral Culture

The original gold standard for HSV diagnosis was recovery of infectious virus in cell culture. HSV replicates rapidly in cell culture, typically in 1 to 2 days, and produces a characteristic cytopathic effect (CPE) (Fig. 157-17).[72,224,332] A variety of cell lines (human fibroblasts, A549, and many others) support HSV replication and are utilized by diagnostic laboratories to isolate HSV. Although the presence of HSV is suggested by the cell types infected as well as the character and timing of the CPE, definitive identification of the infecting virus is accomplished via microscopy of fixed cells with immunofluorescence assay with HSV-1– and HSV-2–specific antibodies.

Several culture methods that do not rely on the evaluation of CPE have been devised that provide more rapid

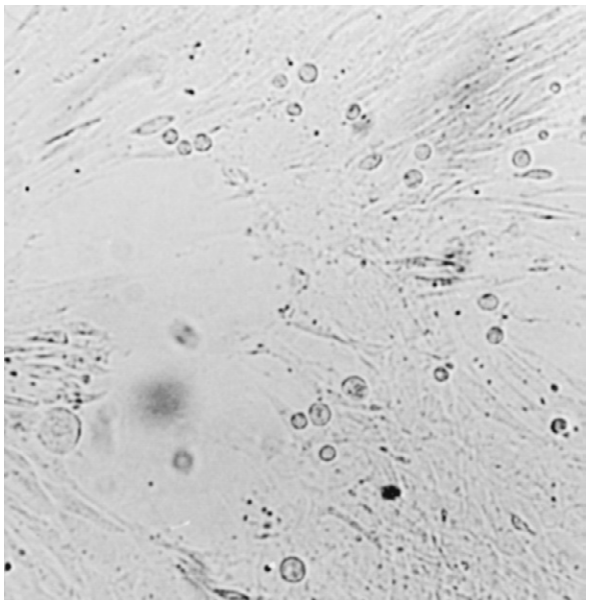

FIGURE 157-17 ■ Culture of HSV on human fibroblasts demonstrating disruption of the cell monolayer and rounding and enlargement of cells to show the cytopathogenic effect.

diagnosis of HSV than traditional culture. One approach is the use of a genetically modified baby hamster kidney cell line containing a reporter gene encoding β-galactosidase under control of an HSV-specific promoter (Enzyme-Linked Viral Inducible System [ELVIS]).[98,231] Addition of a colorimetric reporter substrate after centrifugation-enhanced infection and overnight incubation allows identification of cells infected with HSV. Similarly, the shell vial method utilizes centrifugation-enhanced infection of cell monolayers and overnight incubation, followed by immunofluorescence assay staining with HSV-specific antibodies.[128,180,295,400] Although these methods may reduce the time to result, they are typically less sensitive than traditional cell culture.[81,189]

HSV culture methods, both traditional and rapid, are being phased out by many diagnostic laboratories and replaced by type-specific nucleic acid amplification tests for HSV-1 and HSV-2 DNA. These tests do not show definitively that infectious virus is present in the specimen but suggest that it is or may have been shortly before the specimen was obtained.

Direct Detection of HSV-Infected Cells

Direct detection methods allow a diagnosis of HSV infection to be established more rapidly than any available HSV culture method.[16,102,231,345] Direct immunofluorescent assay of cells taken from mucocutaneous lesions is the procedure used most commonly. Specimens are obtained by unroofing the lesion, swabbing the exposed base to remove infected cells, and transferring the swab to viral transport media. The collected cells are centrifuged and washed, applied to a glass slide, then fixed and stained with fluorescently labeled, HSV-specific antibodies. This method, the direct viral examination or direct fluorescent antibody (DFA) testing, yields sensitivities, when compared with traditional viral culture, in the range of 61 to 80 percent with few false-positive reactions.[72,81] To optimize DFA performance, diagnostic laboratories set criteria for specimen adequacy (e.g., requiring a certain number of basal, parabasal, and intermediate cells from lesion sites), thereby emphasizing the importance of proper specimen collection. Despite these precautions, direct detection of HSV by immunofluorescence remains less sensitive than culture. Because of this, it is recommended that DFA-negative lesional samples be tested by a more sensitive method to rule out false-negative results.[72]

HSV antigens can be detected directly in clinical specimens by a variety of additional methods including enzyme-linked immunosorbent assays (ELISAs) and immunoperoxidase assays.* However, these assays have been replaced in the diagnostic laboratory by nucleic acid amplification tests.

Nonspecific methods such as Papanicolaou (Pap) staining or the Tzanck test have been used in the past to suggest possible HSV infection. Even though these methods may show cytologic changes in specimens obtained from suspected HSV lesions, the diagnosis of HSV should not rely on these methods in current practice because rapid, specific methods are available. Although cytologic examination of HSV lesions reveals typical giant cells and, less commonly, Cowdry type A intranuclear inclusions, these changes also are seen with CMV and VZV. Cytologic changes are identified in approximately 70 percent of culture-positive specimens, but sensitivity is dependent on the experience of the examiner and may be low.[268,359] Electron microscopy of vesicular fluid or tissue preparations may reveal the characteristic virus of the herpes family (Fig. 157-18). However, the microscopist cannot differentiate HSV from other herpesviruses, and this diagnostic approach rarely is available as a rapid method. Because selection of antiviral therapy for herpesviruses requires specific identification of the infecting virus, nonspecific methods have limited clinical value in the current era of specific antiviral therapy.

Polymerase Chain Reaction Assays

Type-specific HSV nucleic acid amplification assays, particularly PCR assay, have become the gold standard for HSV diagnosis and have replaced virus culture and direct examination in many diagnostic laboratories. The detection of HSV DNA by PCR is more sensitive than the isolation of virus by culture.[9,24,174,321,329] In one study of mucosal specimens, the ratio of PCR positivity to virus culture ranged from 3.8:1 in the winter to 8.8:1 in the summer. PCR does not require the presence of infectious virus for detection, and this is one of the great advantages and disadvantages of HSV DNA testing. Given the high sensitivity of HSV PCR, false-positive results may occur, particularly if original specimen contamination occurs at time of collection or if cross contamination between specimens occurs during performance of PCR assay. However, the implementation of careful molecular diagnostic workflows and the development of

*References 8, 49, 90, 231, 278, 345, 406.

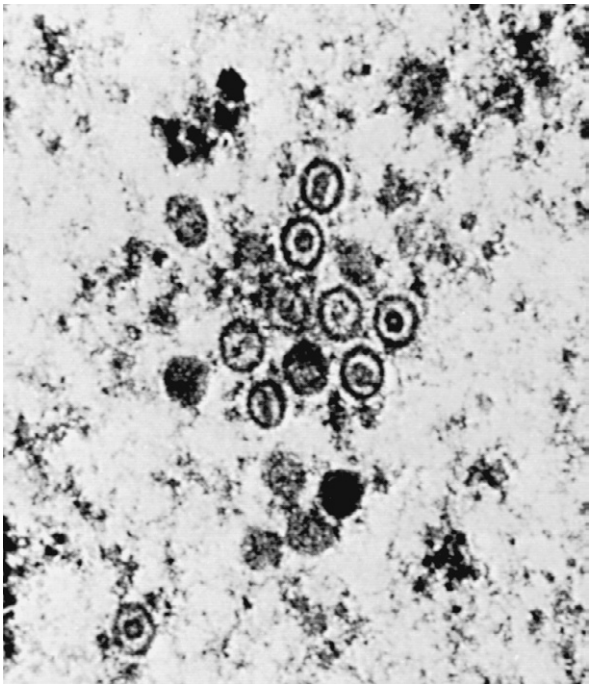

FIGURE 157-18 ■ Electron-microscopic demonstration of HSV particles in a brain biopsy specimen from a 9-month-old infant with HSV encephalitis.

the real-time PCR methodology have considerably reduced the risk for false-positive reactions.

The clinical utility of HSV PCR was first demonstrated for the diagnosis of HSV encephalitis.* Given its high negative predictive value, HSV PCR testing of CSF is often used to rule out HSV infection in patients with suspected herpes encephalitis. However, it is important to recognize that HSV DNA may not be detectable in CSF early in the course of disease.[427] A single negative test should not exclude the diagnosis of HSV when there is high clinical suspicion, and sequential testing of CSF by PCR has rendered the use of brain biopsy unnecessary in most situations. In one study, HSV DNA was detected by PCR in the CSF of 53 (98%) of 54 patients with biopsy-proven herpes simplex encephalitis and was detected in all 18 CSF specimens obtained before brain biopsy was performed on patients with proven herpes encephalitis.[222] Testing febrile neonates with CSF pleocytosis using CSF HSV PCR assay and empirically treating with acyclovir until PCR test results are known has also been shown to save lives and be cost effective.[71]

PCR assay also has demonstrated the presence of HSV DNA in the plasma or whole blood and used to diagnose HSV viremia in neonates, immune-competent patients with eczema herpeticum and primary herpetic gingivostomatitis, as well as in immunocompromised patients with disseminated disease. PCR analysis also may demonstrate prolonged presence of HSV DNA in genital lesions.[89] The sensitivity of the PCR method is adequate for detecting asymptomatic shedding of HSV.[65,88,162] HSV PCR also has utility when the clinical diagnosis is difficult to make, as illustrated by detection of HSV in vitreous fluid[167] and in unusual mucocutaneous lesions in patients with AIDS.[230] HSV DNA may also be quantitated in clinical specimens using PCR-based methods and used to predict severity of disease, especially in hepatitis and encephalitis, and to follow virologic response in these patients.[31,65]

Serologic Diagnosis

Serologic methods are used to assess HSV immune status and document whether an individual has been infected with HSV. Because these viruses cause persistent infections, the presence of HSV IgG antibodies may only signify that the individual has latent HSV-1 or HSV-2 (or both) in sensory ganglia and that the virus can be expected to reactivate and intermittently shed. Clinical laboratories utilize ELISA or immunoblot methods to detect HSV-1 and HSV-2 type-specific IgG antibodies in patient sera. These assays use specific HSV gG antigens and can be used to show whether an individual is infected with HSV-1, HSV-2, or both, but not when the infection was acquired.* If paired sera are available, these assays are capable of demonstrating type-specific seroconversion, even if a patient is already exposed to a single type. The sensitivities of commercial gG type-specific HSV serology tests range from 90 to 98 percent, with specificities greater than 94 percent when compared with Western blot analysis.[414] As with any serologic test, false-negative results are more likely early in the course of infection, and false-positive results may occur in patients with a low pretest probability of exposure.

If a patient is seronegative at the onset of symptoms or at initial evaluation, primary HSV infection can be documented by demonstrating seroconversion with paired sera.[191,208] However, serologic tests are not useful for evaluating HSV recurrence, because IgG antibody titers often do not rise during viral reactivation. On the other hand, increases in IgG antibody titer may occur in the absence of recurrent disease. In addition, testing for IgM antibodies does not improve the serologic diagnosis. HSV IgM assays cannot be used to distinguish primary from recurrent infection because reactivation can also induce the production of IgM antibody.[168]

Local production of HSV IgG in CSF samples can be used to document HSV encephalitis in some patients, but a 2- to 4-week interval is required to demonstrate this change and it cannot be used to guide antiviral therapy.[270,399,404] Testing CSF for HSV IgM antibodies has no demonstrated diagnostic value.

Genetic Analysis for Molecular Epidemiology

HSV DNA from epidemiologically unrelated isolates has a specific cleavage pattern when digested by endonuclease restriction enzymes and subjected to gel electrophoresis (Fig. 157-19).[61] This restriction fragment length polymorphism (RFLP) method is primarily used for

epidemiologic purposes to demonstrate relatedness among isolates during the evaluation of apparent outbreaks or nosocomial transmission events.[61,62,160,241,439] In addition, RFLP analysis has contributed to our understanding of exogenous reinfection versus recurrence and the possibility that individuals may harbor more than one latent virus strain. This method is laborious and not typically performed in diagnostic laboratories. Precise differentiation of HSV strains requires genomic sequencing, which is performed on a research basis.

Antiviral Drug Susceptibility Testing

The persistence of lesions, emergence of new lesions, or increasing plasma viral load despite appropriate antiviral therapy is suggestive of treatment failure and should prompt laboratory evaluation of antiviral resistance. This testing may be useful to guide selection of an alternative therapy, but, unfortunately, testing is not readily available in clinical practice. Although resistance is uncommon in immunocompetent patients (prevalence 0.1% to 0.7%), immunocompromised patients, many of whom receive long-term HSV prophylaxis or treatment, are at relatively high risk for the development of resistance (prevalence 2.5% to 11%).[298] The gold standard method for HSV antiviral susceptibility testing is the plaque reduction assay. This phenotypic assay utilizes Vero cells (African green monkey kidney cells) inoculated with a standardized viral inoculum and incubated for 48 to 72 hours in the presence of serial drug concentrations and no drug controls.[305,385,428] After incubation, the cells are fixed and stained, the number of plaques or focal areas of cytopathic effect is counted, and the concentration of drug that reduces the plaque number by 50 percent (IC_{50}) is calculated. The plaque reduction assay has well-described breakpoint values of 2 μg/mL or greater for acyclovir and 100 μg/mL or greater for foscarnet. Other phenotypic susceptibility methods utilize a variety of techniques to measure HSV replication in culture, including dye uptake, ELISA, DNA hybridization, and PCR assay.[229,298,393,428] Specific breakpoint values will vary based on the assay. Although laborious, phenotypic evaluation remains the primary approach to HSV susceptibility testing in clinical laboratories. Sequence analysis of the genes encoding thymidine kinase *(UL23)* and DNA polymerase *(UL30)*, the targets of HSV antiviral agents acyclovir and foscarnet, have revealed a large number of resistance mutations as well as polymorphisms that do not contribute to the resistance phenotype.[298,237,331] Genotypic susceptibility testing is primarily utilized as a research tool to understand the mechanism of antiviral resistance and is not generally performed for clinical purposes.

PROGNOSIS, COMPLICATIONS, AND SEQUELAE

Most HSV infections occurring beyond the fetal and neonatal periods cause minor morbidity but very rarely are life threatening. The introduction of antiviral drugs that inhibit HSV replication has changed the management and outcome of these infections. Even before these drugs were available, eczema herpeticum resolved without sequelae in most cases. Despite administration of antiviral therapy, HSV encephalitis can be fatal or be associated with serious consequences ranging from moderate to extensive and permanent neurologic disability.[423] The case-fatality rate for untreated encephalitis may be as high as 75 percent,[443] and progressive neurologic damage may occur.[113,157,207] In a series of PCR-diagnosed cases, a Glasgow Coma Scale score lower than 11 was associated with a poor outcome, and the youngest cohort, those younger than 3 years, had higher morbidity and mortality rates.[181] Genital herpes causes significant physical and psychological morbidity. In immunocompromised patients, disseminated HSV infection can result in fatal or serious illness. HSV is one of the most common infectious causes of blindness in developed countries.

TREATMENT

HSV-1 and HSV-2 infections are treated with acyclovir or related drugs. Acyclovir is a nucleoside analog that is a competitive inhibitor of HSV DNA polymerase, and it terminates DNA chain elongation. Acyclovir is an inactive agent. Inhibition of viral DNA synthesis by blocking viral DNA polymerase and DNA chain elongation

requires phosphorylation of acyclovir. HSV-1 and HSV-2 viral thymidine kinases are much more active than are mammalian cell kinases, and acyclovir becomes a specific antiviral agent in the presence of viral thymidine kinase.

Because the oral bioavailability of acyclovir is only approximately 20 percent, efficacy with oral administration requires high and frequent dosing. Concentrations of acyclovir achieved in CSF are approximately 50 percent of plasma levels. Acyclovir is excreted by glomerular filtration, so doses must be reduced in patients with impaired renal function. Acyclovir has been an exceptionally safe drug in clinical practice, but adverse reactions, including rash, nausea, vomiting, diarrhea, abdominal pain, headache, and neutropenia, can occur. Neurotoxicity may occur with an overdose, usually when the dose is not adjusted for poor renal clearance. Acyclovir also can cause acute renal insufficiency by precipitation in the renal tubules in dehydrated patients with high plasma concentrations or by rapid infusion of the drug. Valacyclovir, the L-valine ester of acyclovir, is converted to acyclovir[403] and has much higher bioavailability after oral administration, with plasma concentrations similar to those obtained after intravenous administration of acyclovir. Famciclovir is an oral prodrug of penciclovir[107]; it also is well absorbed orally and is metabolized to the active form on absorption. The major advantage of these agents is that less frequent dosing is required than with acyclovir. HSV-1 and HSV-2 seldom are resistant to acyclovir or related drugs in the immunocompetent host (<1%). Resistance can occur in up to 10% of isolates from immunocompromised patients who receive prolonged antiviral therapy. HSV isolates resistant to acyclovir usually have mutations in the gene encoding viral thymidine kinase *(UL23)* and less often to *UL30*, which encodes for the viral target DNA polymerase enzyme. Foscarnet or, in some cases, cidofovir is an alternative for the treatment of acyclovir-resistant HSV.[42] Resistance to foscarnet and cidofovir has been reported.[298,449]

Oral HSV Infection

Although published experience is limited, administration of oral acyclovir to children with gingivostomatitis is appropriate and can be expected to modify the duration of symptoms if it is initiated early in the clinical course.[177] Several small placebo-controlled trials of primary herpes gingivostomatitis in young children have been reported.[6,11] In one study, the pain and hypersalivation resolved more quickly in acyclovir-treated patients.[120] In a larger study, symptoms resolved more rapidly with a 10-day course of oral acyclovir 600 mg/m^2 four times a day; differences were observed in drooling (4 vs. 8 days with placebo), gum swelling (5 vs. 7 days), speed of healing of intraoral lesions (6 vs. 8 days), appearance of new lesions (57% vs. 94%), and viral shedding in saliva (4 vs. 10 days). Therapy had no effect on the subsequent development of cold sores.[11] A comparison of oral acyclovir suspension, 15 mg/kg five times a day for 7 days, and placebo started within 72 hours documented that drug recipients had a shorter duration of oral lesions (median of 4 vs. 10 days [difference, 6 days; 95% confidence interval (CI), 4.0 to 8.0]) and earlier resolution of other symptoms, including fever (1 vs. 3 days [difference, 2 days; CI, 0.8 to 3.2]), extraoral lesions (0 vs. 5.5 days [difference, 5.5 days; CI, 1.3 to 4.7]), difficulty eating (4 vs. 7 days [difference, 3 days; CI, 1.31 to 4.69]), and difficulty drinking (3 vs. 6 days [difference, 3 days; CI, 1.1 to 4.9]).[6] Treatment also decreased the period of viral shedding (1 vs. 5 days [difference, 4 days; CI, 2.9 to 5.1]). Symptomatic therapy includes antipyretics and oral hydration. The use of oral anesthetics is not recommended and has resulted in self-injury as a result of children chewing on anesthetized oral mucosa or lips.

Although the duration of symptoms is shorter with recurrences, children with frequent or severe recurrences may benefit from treatment with oral acyclovir as soon as new lesions appear. Topical acyclovir has been licensed for the treatment of recurrent oral herpes labialis based on experience in adults. However, its benefits on clinical symptoms are minimal. If treatment in children is indicated, oral acyclovir is the best option. Studies in adult patients with herpes labialis show that patient-initiated, high-dose, short-duration treatment with valacyclovir or famciclovir initiated at the onset of symptoms significantly reduces the time to healing and hastens resolution of pain and tenderness when compared with placebo.[362,364]

Several studies have produced conflicting results regarding the use of topical acyclovir for the treatment of oral herpes recurrences. Topical acyclovir can decrease the duration of HSV shedding from 2 to 3 days with placebo treatment to 1 to 2 days,[367] and the effect on symptoms is either none or subtle (1 less day with vesicles and a 2- to 3-day acceleration of healing). Although no controlled studies have been conducted, acyclovir therapy should be used for the treatment of rare cases of HSV esophagitis in normal hosts.[138]

HSV Keratitis

Children with HSV keratitis should be referred for immediate evaluation by an ophthalmologist who is familiar with this illness and its progressive, sight-threatening forms and with optimal antiviral therapy.[421] The use of cycloplegic and anti-inflammatory agents, which may be necessary, requires specialized experience. Topical preparations have been shown to have a beneficial effect on HSV keratitis and probably other superficial ocular HSV infections such as conjunctivitis and blepharitis.[239] These preparations include idoxuridine (Stoxil), vidarabine (Vira-A), trifluridine (Viroptic), and acyclovir. Neonates with ocular involvement with HSV should also receive both a topical ophthalmic drug and parenteral acyclovir or other antiviral treatment. Orally administered acyclovir also has been used to treat dendritic keratitis, with effects that were similar to those achieved with topical acyclovir in the treatment of dendritic corneal ulceration. Several series suggest that oral acyclovir is therapeutic in patients who have stromal keratitis or keratouveitis.[233,349] When given in conjunction with topical antiviral therapy, the response to oral acyclovir is good, even in those who had failed topical therapy.[350] Oral therapy also is useful for prophylaxis against viral reactivation in those with stromal keratitis,[445] and prophylaxis is associated with decreased recurrence of corneal disease.[454]

HSV Encephalitis

Intravenous acyclovir is the drug of choice for HSV encephalitis.[432] For children 3 months to 12 years of age, 10 to 15 mg/kg/dose every 8 hours is recommended. For children older than 12 years of age and for adults, 10 mg/kg/dose every 8 hours is recommended.[182] Renal function and hydration status should both be monitored closely while the patient is receiving intravenous acyclovir. The recommended duration of therapy ranges from 14 to 21 days or longer and should be determined by clinical response and HSV DNA PCR levels in CSF. Neonates with any form of HSV infection, including encephalitis, should receive parenteral acyclovir until HSV DNA PCR assay of the CSF is negative. Thereafter, oral acyclovir suppressive therapy should be administered at a dose of 300 mg/m^2/dose every 8 hours for 6 months, to improve neurodevelopmental outcomes and prevent skin recurrences.[200]

Two well-controlled clinical studies in Sweden and the United States that compared vidarabine with acyclovir 30 mg/kg/day in three divided doses for 10 to 12 days provided evidence that acyclovir is significantly more effective than vidarabine in treating HSV encephalitis.[356,433] In the Swedish study, the early mortality rate was 19 percent in the acyclovir-treated group and 50 percent in the vidarabine-treated group.[356] The National Institutes of Health collaborative study[433] generated similar data. As was observed in the earlier vidarabine studies,[443] younger age and less severe neurologic signs at initiation of therapy markedly influence the outcome of HSV encephalitis treated with acyclovir. Lethargic patients have a 15 percent mortality rate, whereas comatose patients have a 40 percent mortality rate.

In addition to antiviral therapy, intensive care is required for optimizing the outcome of these patients. Fluid management for the prevention of overhydration or underhydration is critical. Frequently, direct measurement of intracranial pressure is necessary for effective monitoring of increased pressure and treatment with diuretic agents. Anticonvulsant therapy for management of the often severe and prolonged seizures, as well as ventilatory support, usually is necessary at some time during the illness.

Genital HSV Infection

Recommended antiviral therapies for genital herpes simplex infection include acyclovir, famciclovir, and valacyclovir (Table 157-4), but acyclovir remains the best studied drug in children.[79,107] Although topical acyclovir was the first antiviral therapy used to treat genital herpes, it has been replaced by the oral agent. Some benefit was observed with the topical drug, but it is difficult to use, and its effectiveness is limited when compared with oral acyclovir; treatment decreased the mean duration of viral shedding (4.1 vs. 7.0 days with placebo) and time to crusting of lesions (7.1 vs. 10.5 days).[94] In the treatment of recurrent genital disease, topical acyclovir generally tended to have a minor effect on the duration of viral shedding (from 1 to 2 days in treated patients vs. 2 to 3 days in placebo recipients), with little or no effect on symptoms.[247,310] These results were not improved markedly with the immediate use of topical ointment. Early studies in which intravenous acyclovir was given to patients with primary genital HSV infection also were performed.[93,259] When used in a placebo-controlled, double-blind study at a dose of 5 mg/kg every 8 hours for 5 days, acyclovir decreased the duration of viral shedding (2 vs. 8 to 13 days in placebo-treated patients), shortened the duration of local and systemic symptoms by 2 to 5 days, and decreased the time to healing by 7 to 12 days. Complications such as extragenital lesions or urinary retention were reduced significantly.[291]

Oral acyclovir has therapeutic effects on both primary and recurrent HSV infection in adults and should be given to adolescents with these infections. The major effect of intravenous acyclovir therapy on the first episode of genital HSV infection is seen in those who have true primary disease, as opposed to those who have HSV-1 immunity and are experiencing new HSV-2 infection.[291] The intravenous route of administration has been replaced by oral therapy with acyclovir and related agents. In either case, optimal benefit requires early intervention. In a double-blind, placebo-controlled study of patients with primary genital infection, acyclovir at a dose of 200 mg five times per day for 5 to 10 days significantly reduced viral shedding (1 to 6 days vs. 13 to 15 days with placebo), lesion formation after 48 hours (0% to 4% vs. 43% to 44%), the duration of lesions (10 to 12 vs. 16 to 21 days), and the duration and severity of symptoms.[59] In

TABLE 157-4 **Recommended Treatment Regimens for Adults and Adolescents with Genital HSV Infection**

First Clinical Episode
Acyclovir 400 mg orally three times a day for 7 to 10 days
or
Acyclovir 200 mg orally 5 times a day for 7 to 10 days
or
Famciclovir 250 mg orally three times a day for 7 to 10 days
or
Valacyclovir 1 g orally twice a day for 7 to 10 days
Suppressive Therapy
Acyclovir 400 mg orally twice a day
or
Famciclovir 250 mg orally twice a day
or
Valacyclovir 500 mg orally once a day
or
Valacyclovir 1 g orally once a day
Episodic Therapy*
Acyclovir 400 mg orally three times a day for 5 days
or
Famciclovir 125 mg orally twice daily for 5 days
or
Valacyclovir 500 mg orally twice a day for 3 days

*Additional dosing recommendations can be found in the guidelines referenced.

From Centers for Disease Control and Prevention: Sexually transmitted disease treatment guidelines 2010. MMWR Recomm Rep 2010;**59**(RR-12);1-109.

similar studies of adult patients with recurrent genital HSV infection, acyclovir 200 mg five times per day for 5 days decreased the duration of virus shedding (1 to 2 vs. 2 to 4 days), time to healing (5 to 6 vs. 6 to 7 days), and development of new lesions (2% to 10% vs. 19% to 25%), especially when administered early in the recurrence.[277]

In these short-term studies in which patients were cautioned regarding hydration, no significant side effects were observed. Furthermore, no cytogenetic effects were noted.[86] Studies of virus from either placebo or acyclovir recipients showed that 4 to 15 percent of viruses isolated after therapy were more resistant to acyclovir, regardless of therapy.[87] Neither oral nor intravenous acyclovir reduces the rate of recurrence when used to treat either primary or recurrent genital infection. Oral antiviral agents are appropriate for patients who have primary genital HSV infection, HSV proctitis,[79,318] and frequent recurrent disease. Intravenous acyclovir should be reserved for patients who have severe local or disseminated disease with pneumonitis, hepatitis, or meningoencephalitis or complications such as urinary retention or aseptic meningitis syndrome.[79,291]

In adults, valacyclovir administered two times a day was as effective as acyclovir administered five times a day in the treatment of first-episode genital herpes.[131] When compared with placebo, valacyclovir is as effective as acyclovir in suppressing HSV viral replication as measured by culture and HSV PCR assay.[156] Similarly, famciclovir is efficacious in the treatment of first-episode and recurrent genital HSV infection.[12,323]

Symptomatic therapy for HSV lesions should be directed toward reduction of local discomfort, promotion of healing, and prevention of autoinoculation and superinfection. Nonspecific creams and ointments probably delay healing and increase risk for the development of maceration and infection. Keeping lesions clean and dry probably is the most important local measure. Urinating sometimes is painful and can be made less so if done in a bathtub or sitz bath. Some experts advise Burow solution sitz baths or short compress treatments. Prolonged soaking delays healing.

Mucocutaneous HSV Infection in Immunocompromised Hosts

Acyclovir and related drugs given orally or intravenously are the agents of choice for serious mucocutaneous HSV-1 or HSV-2 infection in high-risk hosts. Early initiation of treatment provides the best outcome. Given the limited oral bioavailability of acyclovir, higher plasma concentrations can be achieved with valacyclovir or famciclovir, but clinical experience with these drugs remains limited in children. If the infection is considered potentially life threatening, intravenous acyclovir is the treatment of choice. Therapeutic responses to HSV infection in immunocompromised hosts have been difficult to study because of the variable nature of the disease. The historical experience with vidarabine demonstrated the benefits of antiviral therapy initially. In a randomized, controlled, crossover study of mucocutaneous HSV infection, vidarabine 10 mg/kg/day intravenously in a 12-hour infusion was shown to decrease pain and induce defervescence in patients older than 40 years. In none of the 85 patients in this study did visceral dissemination of HSV develop. However, these observations are of historical interest now because the drug is not available and has been replaced by acyclovir. Acyclovir ointment appears to have some minor effects on pain, viral shedding, and time to complete healing of lesions in immunocompromised persons with mild, non–life-threatening mucocutaneous HSV infection,[440] but oral acyclovir is more effective for mild illness.

Patients with more severe illness should receive care in a hospital setting with the intravenous preparation. Intravenous acyclovir has been analyzed extensively in immunocompromised patients with mucocutaneous HSV infection.[137,317] When used early, acyclovir arrests the progression of infection. In several double-blind, placebo-controlled studies, acyclovir has been shown to be highly effective. It decreased the time to cessation of new lesions (1 vs. 3 days with placebo), time to lesion crusting (3 to 7 vs. 9 to 14 days), time to lesion healing (12 to 14 vs. 18 to 28 days), cessation of pain (4 to 10 vs. 7 to 16 days), and termination of viral shedding (3 vs. 14 to 17 days).[413] Acyclovir administered intravenously is the most effective agent and the drug of choice for treating HSV in an immunocompromised host. The dosage is 250 mg/m^2 or 5 to 10 mg/kg/dose every 8 hours infused over a 1-hour period. In patients with severe disease, the dose may be doubled. The major toxic effect has been renal, with reversible obstructive nephropathy and transient rises in serum creatinine levels (5% to 10% of patients). Adequate hydration, keeping urine specific gravity measurements less than 1.010, usually prevents this problem. Dosage guidelines have been established in patients who have impaired renal function (Table 157-5). One to 5 percent of patients may experience nausea and vomiting. Less commonly (1%), reversible neurologic symptoms (lethargy, agitation, tremor, disorientation, coma, transient hemiparesthesia) and laboratory abnormalities (abnormal EEG, increased CSF myelin basic protein) have developed in bone marrow transplant recipients. These patients usually had received interferon and CNS chemoprophylaxis for leukemia.[412] Other less serious problems include phlebitis (14%) and hives (5%).

Several studies have focused on the use of oral acyclovir in this patient population.[377] The IC_{50} of acyclovir generally is 0.1 to 0.5 μg/mL for HSV-1 and 0.5 to 2 μg/mL for HSV-2. Many studies use molar concentrations; in the case of acyclovir, the dose in micromoles divided by 4 equals the dose in micrograms per milliliter.

TABLE 157-5 **Guidelines for Dosing Intervals of Acyclovir in Patients with Renal Impairment***

Creatinine Clearance (mL/min/1.7 m^2)	Dose	Dosing Interval (hr)
≥50	Normal	8
25-50	Normal	12
10-25	Normal	24
0-10	50% of normal	24

*A dose should be administered after each dialysis session in patients undergoing hemodialysis.

Whereas peak serum levels with intravenous acyclovir vary from 8 to 15 μg/mL, the levels achieved with oral therapy are considerably lower (1 to 2 μg/mL). In preliminary studies of relatively small populations of immunocompromised adults, oral acyclovir at doses of 200 mg five times per day effectively promoted the healing of lesions and inhibited viral shedding.[377] Pediatric studies have used oral doses of 600 mg/m^2 given four times per day.[381] The relative efficacies of oral and intravenous acyclovir have not been compared in this setting. The choice of route of administration requires clinical judgment about the degree of immunosuppression, assessment for evidence of dissemination, and frequent reevaluation if oral drug is given.

Preliminary pharmacokinetic information regarding valacyclovir in immunocompromised children is available.[266] Valacyclovir was administered to 28 immunocompromised children aged 5 to 12 years in an open-label, randomized, dose-ranging study. Doses of valacyclovir administered were 250 or 500 mg twice a day or 500 mg three times a day. Pharmacokinetic evaluation has estimated that the bioavailability of oral valacyclovir is twofold to fourfold greater than that of oral acyclovir. The information provided in this study provides preliminary guidance for dosing of oral valacyclovir in children; however, more studies are needed to determine efficacy and safety in children. Recently published data regarding the pharmacokinetics of valacyclovir suspension in children suggest that valacyclovir oral suspension at doses of 10 and 20 mg/kg administered two to three times daily in children 3 months to 12 years of age produces drug levels similar to doses of 500-mg and 1000-mg caplets, respectively in adults.[198] Pharmacokinetics of famciclovir in children are also being evaluated with a recently proposed dosing scheme that awaits formal clinical evaluation.[43]

All studies of acyclovir in immunosuppressed patients have documented the propensity of recurrent lesions to reappear when therapy is withdrawn. Whether acyclovir reduces the humoral and cellular immune responses to HSV is not certain.[411]

Neonatal Herpes Simplex Virus Infection

Antiviral therapy for neonatal HSV disease significantly improves mortality rates and long-term outcomes of infected neonates. Historically, vidarabine was the first commercially available drug for the treatment of neonatal HSV disease. Placebo-controlled trials demonstrated that vidarabine at doses of 15 or 30 mg/kg/day given as a 12-hour infusion significantly reduced the mortality rate from 62 percent in historic cases and placebo controls to 35 percent in treated cases and increased the percentage of normal survivors from 19 to 43 percent. Results were best in infants with disseminated infection and disease localized to the CNS, with the mortality rate being reduced from 70 to 40 percent and the percentage of normal survivors increased from 10 to 30 percent. No difference was found between the 15-mg and the 30-mg dose in side effects, but the higher dose appeared to inhibit more effectively the progression of disease from skin-eye-mouth involvement to disseminated or CNS disease. None of the 49 treated patients had significant adverse clinical reactions or laboratory abnormalities attributable to the drug. On the negative side, 21 percent of infants progressed to more serious disease while receiving therapy and serious neurologic sequelae developed in 27 percent of the total. Fifteen percent of infants with disseminated or CNS disease continued to excrete HSV in the throat after 10 days of therapy.

The results of a vidarabine-acyclovir comparison trial in the treatment of neonatal herpes did not show any difference in efficacy and safety between the two drugs.[434] When the results with vidarabine and vidarabine-acyclovir were combined, the mortality rate was reduced from 49 percent in untreated historical controls to 17 percent in treated patients. Normal survivors increased from 26 to 67 percent. Although the results in the total group of patients were encouraging, the outcome in the group of patients with disseminated disease was not: a mortality rate of 54 percent in treated patients versus 76 percent in untreated historical controls and normal development in 59 percent of treated survivors versus 54 percent of controls. Factors that predicted mortality and their relative risk were as follows: disseminated disease, 33; CNS disease, 5.8; semicoma or coma, 5.2; disseminated intravascular coagulation, 3.8; prematurity, 3.7; and pneumonitis, 3.6.[435] Factors significantly associated with neurologic sequelae in survivors and their relative risk in these studies were as follows: skin-eye-mouth disease with three or more recurrent skin lesions after completion of acute therapy, 21; skin-eye-mouth disease caused by HSV-2, 14; HSV-2 infection, regardless of disease category, 4.9; CNS disease, 4.4; and seizures, 3.0. In infants with HSV disease limited to the skin, eye, or mouth, neonates with HSV-1 infection were all normal developmentally at 1 year of age as compared with 86 percent of those with HSV-2 infection. Among the latter infants, those with impaired neurologic outcome were significantly more likely to have had three or more skin recurrences in the first 6 months of life.

Because of greater ease of administration, intravenous acyclovir has supplanted vidarabine as the drug of choice for the treatment of neonatal HSV infection. Vidarabine no longer is available commercially. Because mortality and morbidity in neonates with HSV infection remained high using standard (30 mg/kg/day) dosing of acyclovir for 10 days, intermediate-dose (45 mg/kg/day) and high-dose (60 mg/kg/day) intravenous acyclovir for 21 days in 79 neonates was evaluated to treat neonatal HSV infection. Data were compared with those of a previous study in which all infants received standard doses of acyclovir (30 mg/kg/day) for 10 days. Overall, after stratification for disease category, the survival rate for patients treated with high-dose acyclovir was significantly higher than that for patients treated with the standard dose. Specifically, in neonates who received high-dose acyclovir, those with disseminated disease but not encephalitis had a significantly higher survival rate. The mortality rate at 24 months for patients with disseminated disease who received 21 days of high-dose acyclovir was 31 percent, compared with 57 percent for patients who received an intermediate dose for 21 days and 61 percent for those

who received the standard dose for 10 days in the earlier study. For encephalitis, the mortality rate of infants at 24 months was 6 percent with high-dose acyclovir, 20 percent with the intermediate dose, and 19 percent with the standard dose. In addition, recipients of high-dose acyclovir had less morbidity than did historical control infants who received the standard dose of acyclovir. Patients treated with high-dose acyclovir were 6.6 times as likely to have normal development at 12 months of age. Among infants with encephalitis, however, 31 percent of high-dose acyclovir recipients were developing normally at 12 months as compared with 29 percent of patients treated with the standard dose. With respect to toxicity in the high-dose acyclovir recipients, 21 percent had a transient neutropenia that resolved either during continuation of high-dose acyclovir or after its cessation. Nephrotoxicity occurred in four (6%) infants who had disseminated disease. Because acyclovir is eliminated by the kidneys, the dose should be adjusted for renal disease. High-dose acyclovir did not impede the development of an adequate antibody response to HSV in infected infants.

These studies have led to the current recommendation for the use of intravenous acyclovir at a dose of 60 mg/kg/day for a minimum of 21 days to treat neonatal CNS and disseminated HSV disease and a minimum for 14 days for skin-eye-mouth disease.[5] In addition, infants with ocular involvement should receive a topical ophthalmic drug (1% to 2% trifluridine, 1% idoxuridine, or 3% vidarabine), in addition to systemic acyclovir. Consultation with an ophthalmologist is also recommended to assist in the management of ocular HSV in the neonate, because corticosteroids and other medications may be indicated in some patients to preserve vision. All patients with HSV CNS infection should have a repeat lumbar puncture performed at the completion of acyclovir therapy to determine resolution of abnormal CSF parameters and to document whether the CSF specimen is HSV culture and/or HSV DNA PCR negative. A positive result from a CSF HSV PCR assay at the end of 21 days is an indication for continuing intravenous acyclovir therapy and for performing repeat neuroimaging studies to evaluate the extent of CNS damage. Repeat samples of blood and CSF should be obtained weekly until HSV studies are negative and provide a guideline for duration of antiviral therapy.

Concern has been raised that some infants may have progressive neurologic injury after acquiring neonatal herpes encephalitis. In addition, infants who have three or more skin recurrences with HSV-2 in the first 6 months of life have been shown to be at increased risk for having neurodevelopmental abnormalities at follow-up, whether as a consequence of previously undetected CNS infection or because of CNS dissemination during skin reactivation. Suppression of HSV skin reactivation by the administration of acyclovir (300 mg/m^2 per dose given orally three times daily) for 6 months is recommended.[5] Oral suppression for 6 months also improves neurodevelopmental outcome in neonates with all forms of HSV infection. The infant's blood cell counts should be monitored while receiving long-term oral acyclovir therapy because documented suppressive therapy resulted in neutropenia in 50 percent of treated infants. In addition, emergence of acyclovir-resistant HSV isolates has been documented. Acyclovir suppression also has been used after development of HSV eye infection in which reactivation might imperil vision.

General supportive measures, such as maintenance of fluid and electrolyte balance, correction of hypoglycemia, management of disseminated intravascular coagulation and shock, control of seizures with anticonvulsants, mechanical support of the respiratory system, nutritional support, and antimicrobial therapy for complicating bacterial infections, also are critical in improving the outcome for neonates with HSV infection. Because neonates with a disseminated form of HSV with hepatitis and hepatic necrosis may have secondary peritonitis and gram-negative bacteremia or sepsis, administration of antibiotics is also recommended. In severe cases of hepatic failure associated with neonatal disseminated HSV infection, liver transplantation has been effective treatment for some infants.[260,313]

Acyclovir-Resistant HSV Infection

Despite its widespread use, acyclovir remains an effective antiviral compound. In immunocompetent hosts, acyclovir resistance has been an unusual problem, even with prolonged courses of suppressive therapy. Mutant, thymidine kinase–negative virus strains have been recovered in 3 to 10 percent of patients treated with acyclovir, but acyclovir-resistant virus also can be recovered in placebo-treated patients, thus indicating that subpopulations of HSV are present in the lesions.[87] Thymidine kinase–negative HSV recurrences in immunocompromised patients have been documented well, with demonstration of the ability of these viruses to establish latency and recur. These viral mutants are less virulent in animal models. Patients who were culture positive for such mutants often have thymidine kinase–positive HSV isolates recovered from lesions during their next recurrence.[354]

Acyclovir-resistant virus occasionally has been shed by immunocompetent patients before, during, or after receiving therapy, yet it usually has not been associated with treatment failure.[155,212,234,378] In pretreatment patients, 3.6 percent of isolates (31 of 870) were resistant to acyclovir (not inhibited by 3 μg/mL). A similar percentage (3.1%) of resistant isolates was recovered from 663 immunocompetent patients after administration of acyclovir therapy.[87] An immunocompetent patient was reported who had an acyclovir-resistant virus containing an altered thymidine kinase that caused multiple recurrences of genital herpes unresponsive to acyclovir therapy.[212] In another immunocompetent patient receiving prophylactic acyclovir for recurrent genital herpes and long-term prednisone therapy for chronic urticaria, recurrent genital lesions with acyclovir- and penciclovir-resistant HSV-2 developed.[214] To date, these occurrences remain rare findings in the immunocompetent patient population. Acyclovir-resistant HSV has also been documented in neonates treated for HSV infection.[238]

Drug resistance occasionally is a problem in the acyclovir-treated immunocompromised population. Cases of acyclovir-resistant virus causing local inva-

sive disease and, less commonly, dissemination and acyclovir-unresponsive meningoencephalitis have been reported.[137,140,244,326] Recurrences with acyclovir-resistant HSV-1 may be encountered, as described in a child with Wiskott-Aldrich syndrome.[330,331] Of the three mechanisms of altered sensitivity of HSV to acyclovir (absent thymidine kinase [TK^-], altered thymidine kinase [TK^A], and altered viral DNA polymerase), the TK^- type is encountered in the vast majority of cases.[87,137,140] These viruses cannot phosphorylate acyclovir and convert it to the active triphosphate. Among bone marrow transplant recipients receiving multiple courses of acyclovir, acyclovir-resistant virus was recovered from 2 percent of patients during initial therapy and from 9 percent after treatment of a second recurrence. In a tertiary care center, acyclovir-resistant, clinically significant virus was recovered from 5 percent of immunocompromised patients (usually after receiving acyclovir) but not from any immunocompetent hosts.[125] Illness caused by acyclovir-resistant viruses was more severe in pediatric patients and occurred more commonly in very immunocompromised patients, such as those with AIDS or those who had undergone bone marrow transplantation.[126] Among bone marrow transplant recipients and patients with AIDS who were tested after receiving acyclovir therapy, 18 percent (105 of 582) had isolates that were acyclovir resistant.[87] In vitro viral susceptibility of HSV has been highly associated with clinical response to acyclovir in HIV-infected patients.[327] Acyclovir-resistant isolates are resistant to penciclovir and ganciclovir, which also require phosphorylation. Foscarnet has been used and is associated with successful clinical response and cessation of viral shedding. The most common side effects of foscarnet are nephrotoxicity (azotemia), alterations in serum calcium and phosphorus, and neutropenia, which has been observed in 10 to 25 percent of patients.[190,326] Foscarnet therapy is indicated for an immunocompromised patient who has HSV infection unresponsive to acyclovir. Viral susceptibility testing may aid in clinical management.[298,328]

In patients receiving chronic or multiple courses of foscarnet, foscarnet-resistant HSV isolates (IC_{50} >100 μg/mL) have been recovered from lesions failing to respond to foscarnet.[327,328] Of note, these lesions often responded to acyclovir, alone or in combination with foscarnet.[328] Perhaps the mutation in DNA polymerase responsible for foscarnet resistance was in an area not related to acyclovir activity. Other experimental strategies used to treat acyclovir-resistant viruses have included high-dose, continuous-infusion acyclovir (1.5 to 2.0 mg/kg/hr) or intravenous cidofovir,[58,125,223,358] although recent cases of cidofovir-resistant isolates have been reported.[449] In the case of acyclovir- and foscarnet-resistant viruses, topical 3-hydroxy-2-phosphonomethoxypropyl cytosine (HPMPC or cidofovir) or a combination of topical trifluorothymidine and interferon-α[40,325,330] has been used successfully in patients with chronic mucocutaneous lesions.

PREVENTION AND INFECTION CONTROL

Because HSV infection is ubiquitous in the human population and intermittent asymptomatic shedding is extremely common, preventing transmission of HSV is difficult. By diminishing the passage of infectious HSV-2, condoms offer moderate protection and should be recommended routinely.[251,416] Circumcised males are also less likely to acquire HSV-2 infection compared with uncircumcised controls.[395]

HSV is sensitive to heat and lipid solvents, so the use of antiseptics, soap and hot water, or chlorine decreases the risk for transfer of virus in settings such as the home, spas, pools, wrestling meets, and hospitals. In addition, appropriate use of gloves and other personal protective wear, by all health care personnel who come in contact with potentially infected body secretions or rashes should decrease the acquisition and health care–associated transmission of HSV. Health care workers with an active herpetic whitlow should wear gloves and not have direct patient care responsibilities for neonates and immunocompromised patients.[5] Health care workers with active oral herpes lesions should practice good hygiene and precautions, and reassignment to non–patient care areas should be made on an individual basis. Health care providers should wear gloves and wash carefully before and after contact with respiratory or genital tract secretions. Parents and caretakers of infants with eczema or severe diaper rash should be especially careful to avoid making direct or indirect contact of this altered skin with an active HSV lesion. Burn patients should be protected against exposure to or direct contact with personnel or visitors who have active HSV lesions. Immunosuppressed patients with evidence of HSV infection usually are experiencing reactivation of latent virus. Primary HSV infections in immunosuppressed persons, as in neonates, may be especially severe, and protecting these susceptible patients against exposure to HSV lesions is important. Wrestlers and rugby players who have exposed skin lesions caused by HSV should be excluded from competition.

The major approaches to the prevention of neonatal herpes involve interruption of transmission from sites of HSV infection and disease at the time of delivery and postnatally from a variety of potential sources. Because in utero transplacental congenital infection occurs so infrequently and predicting the occurrence of congenital infection during pregnancy is not possible, no standard recommendations for prophylaxis are available.

Cesarean delivery within 4 hours of rupture of fetal membranes in a mother with active genital herpes at the time of delivery is recommended to reduce the risk for natal infection. Because serial vaginal cultures taken during the latter stages of pregnancy have failed to predict shedding at the time of delivery, such monitoring is not recommended. Cesarean delivery is recommended only for women with active vesicular or ulcerative lesions at the time of delivery.[5] Cesarean delivery is not always 100 percent protective, even if the membranes are intact. Between 1.2 and 3 percent and, in one study, up to 33 percent of neonates with HSV infection are delivered by cesarean delivery. The cost-effectiveness of performing a cesarean delivery in women with recurrent lesions at delivery has been questioned by some experts, but it remains the current recommendation in the United States. Multiple clinical trials have shown that administration of prophylactic acyclovir and valacyclovir beginning at 36 weeks' gestation reduces the risk for clinically apparent HSV

genital vesicles and ulcers at delivery, reduces the risk for HSV viral shedding at delivery, and also reduces the incidence of cesarean delivery. However, although the hope is that the risk for HSV disease in the neonate also would be reduced, in none of these studies was sufficient power or evidence available to determine the effect of peripartum prophylaxis on the incidence of neonatal HSV. No adverse effects have been seen in infants exposed to maternal acyclovir during pregnancy. Because fetal scalp electrode monitor, forceps, and maneuvers that might cause a break in the infant's skin during delivery appear to increase the risk for acquisition of neonatal HSV, they should be used only with clear indication and a careful assessment of the risk-to-benefit ratio.

The results of antenatal genital HSV cultures from pregnant women with a history of genital herpes do not predict the infant's risk for exposure to HSV at delivery. Because 60 to 80 percent of mothers of infants with neonatal herpes are asymptomatic or have unrecognized infection, the optimal approach may be to perform a screening test to identify women shedding or likely to shed HSV at the time of delivery. Although HSV rapid antigen-detection tests continue to be developed commercially, their sensitivity in *asymptomatic* women still is only 60 to 75 percent. Screening of pregnant women for non–type-specific HSV antibody would be confounded by the presence of HSV-1 antibody, which is present in 60 to 80 percent of the population. The presence of HSV-1 antibody probably represents oral herpes, which poses little risk to the neonate. Although type-specific antibody assays are available to identify pregnant women infected with HSV-2, such an approach would miss women with genital HSV-1 infection or those with asymptomatic primary HSV-2 infection near the time of delivery before antibody is detectable. Its use has been recommended in identifying discordant couples, that is, women with no history of having genital HSV infection but whose sexual partner has had previous infection, so barrier precautions may be used before delivery to decrease the chance of development of a maternal primary infection that poses a greater risk to her infant. Culturing the genital tract of women at the time of vaginal delivery would identify infants exposed to HSV and allow anticipatory management. However, because genital HSV infection rates are only 0.1 to 0.4 percent, this approach likely would not be practical or cost effective for *all* women. Culturing of *selected* women at delivery could focus on (1) positive or partner-discordant HSV-2 serologic tests, (2) those women with a history of genital herpes in themselves or their sexual partners, (3) those women with a history of another sexually transmitted disease or multiple sexual partners, and (4) mothers with a history of maternal fever in labor. However, routine or selective serologic screening, although recommended by some experts, is not currently a standard recommendation, and further investigation is required to determine whether screening of pregnant women to prevent neonatal herpes is beneficial, practical, and cost effective.

No studies have been conducted on the optimal management of asymptomatic infants exposed to maternal HSV infection at delivery, although guidelines on maternal and neonatal evaluation and prophylactic or anticipatory antiviral therapy are available.[197a] A recently published algorithm for the evaluation of asymptomatic neonates following vaginal or cesarean delivery to women with active genital herpes lesions recommends the following approach:

Obstetricians who note a visible lesion should obtain a swab for HSV culture and HSV PCR and determine maternal history of genital HSV preceding pregnancy.

If there is a positive maternal history of prior genital HSV, HSV surface cultures and PCR, and blood PCR should be obtained from the asymptomatic infant at 24 hours of age. If the mother has recurrent infection, the risk of neonatal disease is probably less than 3 to 5 percent. Acyclovir does not need to be initiated if the infant remains asymptomatic. If the laboratory studies from the infant are negative, then the family is educated regarding signs and symptoms of neonatal HSV disease and the infant is followed closely. If any of the infant testing is positive, then further evaluation is performed and intravenous acyclovir is initiated.

If there is no maternal history of prior genital HSV, then it is recommended that type-specific serology for HSV-1 and HSV-2 antibodies be sent from the mother. At 24 hours of age, HSV surface cultures and HSV PCR, HSV blood PCR, CSF studies, and serum ALT should be obtained from the infant. Intravenous acyclovir at 60 mg/kg/dose in three divided doses is then initiated pending results of maternal serology. The duration of treatment is dependent on whether maternal lesion culture and PCR are positive and whether maternal serology reflects first episode primary, first episode nonprimary, or recurrent infection. If maternal serology is consistent with primary or first episode nonprimary infection at delivery, the neonatal infection rate may be as high as 30 to 50 percent.

It is recommended that this management algorithm be used only in facilities where access to PCR and type-specific serologic testing is readily available and turnaround time for test results is reasonably short. In addition, evaluation and treatment is indicated in any infant before 24 hours of age if signs and symptoms of HSV disease are present. Immediate evaluation and treatment may be considered if infant is preterm (≤37 weeks' gestation) or there was prolonged rupture of membranes (>4-6 hours). Situations that increase the risk for neonatal transmission despite maternal recurrent disease include prematurity, the use of a scalp electrode monitor, or skin lacerations. All infants should be monitored closely for any clinical evidence of HSV infection. Any positive culture or the occurrence of signs or symptoms suggesting HSV infection in the neonate suggests that a full virologic evaluation, including blood and CSF analysis for HSV by PCR, should be performed and antiviral therapy initiated. Antiviral therapy also should be administered to neonates with positive HSV cultures of mucosal sites, and these neonates should not be assessed as being merely colonized, because all require intravenous acyclovir therapy.[5] Breast-feeding is contraindicated only if the mother has a vesicular lesion on her breast. Physicians also have recommended that circumcision be delayed for 1 month in infants at highest risk for transmission.

Prevention of postnatally acquired neonatal infection needs to take into account the potential sources of HSV: (1) maternal oral herpes or breast lesions; (2) household

member, such as father or sibling, or other close contact, such as grandparent or caretaker, with oral herpes or herpetic gingivostomatitis; and (3) health care–associated transmission from other infected infants or health care workers. Transmission to the neonate from family members with oral herpes lesions can be interrupted by education, avoidance of kissing and nuzzling of the neonate if they have oral herpes ulcers or history of "cold sores," and avoidance of touching the neonate if they have a herpetic skin lesion or whitlow, as well as common-sense personal hygiene, including hand washing. Health care–associated transmission can be reduced by contact isolation and hospital infection control measures, as well as universal precautions and good hand washing techniques. Personnel with herpetic whitlow should not have direct patient care responsibilities until the lesion has healed. Infants with HSV infection should be placed in contact isolation for the duration of the illness.[5] The median duration of viral shedding from skin vesicles and mucosal sites in infants receiving acyclovir is 5 to 8 days. Asymptomatic but high-risk infants born to mothers with herpes at delivery also should be in contact isolation; alternatively, they may room in with the mother in a private room.

Immunoprophylaxis and Chemoprophylaxis

The development of vaccines is a long-term objective that has significant potential to ameliorate the disease burden associated with HSV-1 and HSV-2.[14] However, to date, attempts to create effective HSV vaccines have met with limited success.[37,257,320,369] In one early report, a vaccine containing the recombinant glycoprotein D of HSV-2 (gD_2) was used in patients who had established recurrent genital herpes infections, and vaccine recipients had a third fewer genital herpes recurrences than those experienced by placebo recipients during the study year.[374] However, experience with the use of recombinant vaccines to prevent primary HSV infections has yielded mixed results. Recombinant HSV-2 gD_2 and gB_2 have been demonstrated to induce high humoral and cell-mediated immune responses in seronegative and seropositive recipients.[227] Some vaccines may protect women who have no HSV immunity at baseline.[369] In a study of discordant couples, an HSV-2 gD_2 subunit vaccine with alum and monophosphoryl lipid adjuvant was approximately 73 percent effective in preventing symptomatic genital HSV-2 disease in women who were seronegative for both HSV-1 and HSV-2.[371] However, when the same vaccine was given to 8323 women who were negative for antibodies to HSV-1 and HSV-2 in a randomized double-blind efficacy field trial, the vaccine was not efficacious, presumably owing to differences in the populations studied.[37] These studies illustrate that high levels of neutralizing antibody do not guarantee protection against infection. Other vaccine types in early stages of development include disabled infectious single-cycle virus vaccines, live genetically attenuated vaccines, and naked DNA.[369,442] No adequate controlled trials of high-dose intravenous immune globulin as an intervention to suppress frequently recurring genital herpes have been reported, and this method is not likely to be effective because infected patients have high titers of HSV-specific antibodies.[252]

Intramuscular human interferon-α administered before and after surgery on the trigeminal nerve root significantly decreased the incidence of HSV shedding and clinical reactivation.[290] In similar studies, interferon had no significant effect on HSV shedding or reactivation in renal transplant patients.[83]

Intravenous acyclovir has been shown to prevent reactivation of HSV almost completely in immunosuppressed patients receiving a bone marrow transplant or antileukemic chemotherapy.[336] In patients with bone marrow transplants, intravenous therapy is begun at the onset of immunosuppression and continued through the immediate transplant period, and then therapy is switched to oral acyclovir for several months.[145] Oral acyclovir administered chronically markedly suppressed recurrence in immunodeficient patients.[386] The use of prophylactic acyclovir is indicated in HSV-seropositive, immunosuppressed pediatric patients. Long-term use of suppressive prophylactic acyclovir appears to prevent the emergence of drug-resistant HSV disease in hematopoietic stem cell transplant recipients.[107,127]

Oral acyclovir 200 mg two to five times per day administered chronically can prevent reactivation of genital HSV nearly completely in patients with frequent recurrences. Recurrences decreased by 50 to 70 percent, and the time to recurrence changed from 14 to 25 days in patients receiving placebo to 100 to 125 days in those receiving acyclovir.[116,378] Breakthrough recurrences tended to be mild and to have less viral shedding and rarely were caused by acyclovir-resistant virus. When acyclovir was discontinued (after 12 to 15 weeks of administration), HSV recurrences reverted to the pretreatment frequency. Higher doses of acyclovir suppressed recurrences in patients experiencing a "breakthrough" with more conventional doses. In patients receiving therapy for 5 years, the number of recurrences declined from the first year (1.7) to the fifth year (0.8). Twenty to 25 percent of patients are recurrence free for 4 to 5 years.[146] After prophylactic therapy ended, suppressive therapy no longer was warranted in some patients because of longer periods between recurrences.[132,375] Patients who had resistant virus exhibited re-isolation of acyclovir-sensitive virus. Thus, acyclovir suppressed recurrences without eliminating latent virus. One study has reported that acyclovir does not seem to change the rate of asymptomatic viral shedding.[376] A subsequent study demonstrated that acyclovir 400 mg twice a day resulted in a 95 percent reduction in subclinical viral shedding when compared with placebo in women with genital herpes.[419] Side effects of chronic acyclovir therapy include an increase in mean corpuscular volume and hemoglobin concentration without anemia or megaloblastic changes, neutropenia and asthenia, and mild gastrointestinal upset.[378] Valacyclovir and famciclovir also can be used to suppress frequently recurring genital herpes effectively, and they suppress both symptomatic and asymptomatic HSV shedding.* Both drugs are more expensive than is acyclovir. The decision of

*References 106, 156, 322, 418.

whether to use episodic or suppressive therapy for individuals with recurrent genital HSV infection depends on the frequency of recurrences. Those with a recent primary infection and frequent recurrences may prefer long-term suppressive therapy. If episodic therapy is used, it should be initiated as soon as symptoms begin. Oral herpetic recurrences were prevented in skiers given a brief course of acyclovir during their ski trip.[365]

Chronic antiviral suppressive therapy with valacyclovir reduced genital HSV transmission in heterosexual HSV-2–discordant couples in one study.[95] Once-daily suppressive therapy with valacyclovir or placebo was given to the HSV-2–seropositive partner. Acquisition of HSV-2 occurred in 4 of 743 susceptible partners given valacyclovir and 16 of 741 susceptible partners given placebo (hazard ratio, 0.52). HSV was identified in genital secretions 2.9 percent of days in source partners receiving valacyclovir and 10.8 percent of days in placebo recipients. Use of condoms and abstinence during symptomatic outbreaks still are recommended. Use of HSV type-specific serologic testing to identify HSV-seropositive individuals and disclosure of HSV status, in combination with condom use, risk reduction counseling, and long-term suppressive antiviral therapy have the potential to control the spread of HSV-2 infection.[149,415] The potential utility of antiviral therapy against herpes simplex is being evaluated as a strategy for prevention of HIV infection.[73,74]

The role of antiviral therapy during pregnancy to prevent neonatal HSV infection is undergoing evaluation for safety and efficacy. In one randomized, blinded trial, women with recurrent genital HSV received either acyclovir, 400 mg three times a day, or placebo from 36 weeks' gestation until delivery. Genital lesions were present at delivery in 14 percent of women receiving placebo and 5 percent of women taking acyclovir ($p = .08$). A significant decrease in HSV culture and PCR positivity was noted in the acyclovir group near the time of delivery. No significant difference in delivery by cesarean section was found between the groups. Suppressive acyclovir treatment decreased but did not eliminate genital lesions or HSV viral detection at delivery.[425] Another randomized, placebo-controlled study evaluated the effect of daily valacyclovir suppression initiated at 36 weeks' gestation. Women receiving valacyclovir had fewer recurrences of genital HSV; however, valacyclovir suppression did not decrease the number of women who had viral shedding or lesions near delivery. A limited sample size may have contributed to failure to observe a significant difference in groups treated with drug versus placebo.[10] Neonatal HSV infection may still occur after maternal acyclovir suppression, as illustrated by a recently published case series.[297]

Experience with acyclovir prophylaxis for reactivation of HSV in children is limited. Prophylactic oral acyclovir 30 to 60 mg/kg/day in three to five doses for 1 week has been shown to decrease seroconversion effectively and to eradicate symptomatic cases of HSV gingivostomatitis in a nursery setting in which outbreaks of primary HSV infection were occurring.[219] Suppression, at doses of 300 mg/m^2 three times daily, has been effective in infants with frequent recurrences of HSV after neonatal HSV infection and has been safe, although prolonged use has been associated with reversible neutropenia. To date, prolonged suppressive therapy in adults has not resulted in serious side effects* or an increase in the problem of drug-resistant HSV in a healthy host.

HISTORY

The recorded history of CMV probably began when Ribbert[360] described in 1881 and then reported in 1904 "protozoan-like cells" in the organs of an infant who died of presumed congenital syphilis. In 1921, Goodpasture and Talbot[175] hypothesized that these swollen cells, or "cytomegalia," were host cells that had been injured by a virus. During the first half of the 20th century, CMV was recognizable only by the pathologic changes that it produced in infected cells; and because these cells frequently were seen in the salivary glands of animals and humans, CMV originally was called the "salivary gland virus."

In 1956, human CMV was isolated in tissue culture by independent investigators Rowe and colleagues,[372] Smith,[396] and Weller and associates.[454] Because several human and animal viruses subsequently were found to replicate in salivary glands, the descriptive name *cytomegalovirus* was proposed by Weller in 1960. The ability to cultivate CMV in tissue culture led to the development of serologic techniques, which in the 1960s and 1970s resulted in many important clinical and epidemiologic observations. For example, CMV was found to infect people of all ages throughout the world. By 1962, CMV was established as a significant pathogen of the fetus and neonate that was capable of producing a spectrum of clinical manifestations and neurologic sequelae.[453] In 1966, Kaariainen and colleagues[224] presented evidence supporting CMV as a cause of posttransfusion mononucleosis syndrome.

The molecular biology of the virus was explored during the 1970s and 1980s and continues to be studied by many investigators. In addition, during the 1970s and 1980s, CMV emerged as a major cause of morbidity and mortality in immunosuppressed patients, especially those who underwent organ or marrow transplantation or who had acquired immunodeficiency syndrome (AIDS). In 1976, the first clinical trial of the live attenuated CMV vaccine Towne 125 was reported; since then, more than 500 renal allograft recipients as well as healthy young men and women have received the vaccine under investigational protocols.[156,334] In addition, research on a glycoprotein B subunit vaccine based on one of the glycoproteins of the virus began in the 1980s; and in the 1990s and the early part of the 21st century, other recombinant vaccines were developed and tested in human volunteers. Clinical trials with other vaccines, such as alphavirus replicon particles, live attenuated viral vaccines, and DNA vaccines began in 2005.[424] However, after decades of research, a successful CMV vaccine remains elusive. In 1999, the Institute of Medicine of the National Academy of Sciences assigned a high priority for a vaccine to prevent CMV infection, an action that was quickly endorsed in 2000 by the National Vaccine Advisory Committee, based on the lifetime costs to society and the human suffering associated with CMV disease in neonates and immune-compromised individuals.[24,231] A resurgence of awareness of CMV from public health officials and the lay community began in 2004, providing hope that prevention and treatment of CMV disease may become a priority for research, education, and public health policy.[75] Attempts by clinicians to treat CMV disease began in the late 1960s and early 1970s,[147] and now CMV infection is a treatable disease; several specific and effective antiviral agents, including ganciclovir (licensed in 1989), foscarnet (licensed in 1991), and cidofovir (licensed in 1996), are available to clinicians to treat seriously ill patients.[70] Most recently, in 2000 to 2012, immunomodulating agents, such as CMV hyperimmune globulin and adoptive immunotherapies using CMV-specific cytotoxic T lymphocytes, are being evaluated in clinical trials as adjuncts to available antiviral therapies.

VIROLOGY

CMV is a member of the *Herpesviridae* family of DNA viruses. This family contains many important human pathogens and is subdivided into three subfamilies: (1) *Alphaherpesvirinae*, fast-growing, cytolytic viruses that are latent in neurons and include herpes simplex virus (HSV) types 1 and 2 and varicella-zoster virus (VZV); (2) *Betaherpesvirinae*, slow-growing, cytomegalic viruses that contain the CMVs; and (3) *Gammaherpesvirinae*, herpesviruses that preferentially grow in lymphocytes and sometimes transform them into malignant states; this subfamily includes Epstein-Barr virus and human herpesviruses 6, 7, and 8.

CMV is the largest member of *Herpesviridae*. The genome is double-stranded DNA 240 kb in size (150×10^6 daltons; guanine + cytosine [G + C] content, 58%), and it has a unique long sequence and a unique short sequence, both of which are bounded by repetitive sequences that are inverted relative to each other. The genome, therefore, can assume four isomeric forms. The viral particle has a 110-nm icosahedral capsid composed of 162 capsomeres. The entire virion is enclosed by a lipid envelope, which yields a final diameter of approximately 200 nm.[418]

Replication of CMV is slow compared with that of HSV. Whereas it takes herpes simplex only 4 to 8 hours to produce infectious progeny virus, CMV requires at least 24 hours. The CMV genome is transcribed slowly in a regulated sequence; on the basis of the appearance of different classes of CMV-specific proteins, the replicative cycle can be divided into three periods: immediate-early, early, and late. The immediate-early period is defined as the first 4 hours after infection occurs. During this period, specific segments of the DNA genome undergo restricted transcription and certain regulatory proteins are produced that allow the virus to take control of host-cell macromolecular synthesis. The early period of replication begins after the immediate-early phase and persists for almost 20 hours. This period is characterized by replication of viral DNA, synthesis of infected cell proteins, and production of progeny virus. The late period usually is considered to occur 24 hours after infection develops. During this period, the structural components of the virus are produced and infectious virus is released from the cell. Monoclonal antibodies against the various immediate-early, early, and late proteins produced by CMV have been used as rapid viral diagnostic tools.

CMV has no distinct serotypes. However, strain relatedness or differences can be determined by molecular analysis of viral DNA. Restriction enzyme analysis of DNA extracted from CMV isolates that are linked epidemiologically (e.g., serial isolates from the same person, mother-infant pairs, or family members experiencing temporally related CMV infections) shows identical or similar DNA fragment mapping patterns. This technique or modifications of this technique have been applied to the epidemiology of CMV in a variety of patients, such as transplant recipients, congenitally infected infants, and patients whose CMV was transmitted from person to person in hospitals, daycare centers, and residences. Polymerase chain reaction (PCR) methodology has determined CMV genotypes exist, by showing differences in the a sequence, major immediate-early, glycoprotein B (gB or UL55), H (gH or UL75), N (gN or UL73), and UL144 regions of the viral genome.* Four gB genotypes have been characterized, and although all genotypes cause congenital and acquired infections, studies suggest that adverse outcomes after CMV infection may be linked to infection with a specific gB genotype, but none has been conclusive. Infection with the CMV gB3 genotype appears to be associated more commonly with fatal infections in bone marrow transplant recipients and hearing loss in congenitally infected neonates, and CMV gB2 and gB4 genotypes appear to be more often fatal in patients with AIDS, in some studies.[35,165,348,469,473] Some studies have suggested neonates with gN-4 genotype may have higher risk for sequelae, whereas others have not confirmed this association.[209,330,331] Pregnant women, neonates with congenital CMV infection, healthy toddlers, and immune-compromised patients may harbor more than one CMV genotype and may have different genotypes in different compartments of the body.[123,186,302,371] Mixed gB genotype infections in transplant recipients may be associated with higher viral loads and delayed viral clearance.[270]

EPIDEMIOLOGY

Seroepidemiologic studies have shown that infection with CMV occurs commonly and usually is inapparent.[482] However, the burden of CMV infection and severe disease may be increasing in certain high-risk groups, such as neonates and premature infants and older children and adults with immune deficiencies as well as transplant recipients.[332,387,426] The incidence of CMV infection does not appear to be seasonal. However, the prevalence of CMV IgG antibody is influenced by many factors, including the age, geographic location, cultural and socioeconomic status, race or ethnicity, and child-rearing practices of the group. For example, in developed countries such as the United Kingdom and the United States, the prevalence of CMV antibody is 40 to 60 percent in adult populations of middle-to-upper socioeconomic status and more than 80 percent in lower socioeconomic status groups.[182,412,481] CMV seroprevalence in the United States also may differ by race and ethnicity, with reports of 51 percent of non-Hispanic white individuals being CMV seropositive compared with 76 percent of non-Hispanic black individuals and 82 percent of Hispanic or Mexican Americans.[102,129,415] In contrast, in developing countries, 80 percent of children acquire CMV by the time they reach 3 years of age and almost all persons have been infected by adulthood.[17,25,449] Studies on the age-related prevalence of infection with CMV in the United States suggest three periods of increased incidence of acquisition: early childhood, adolescence, and the childbearing years.[17,455,480]

Pregnancy

Between 45 to 100 percent of women of childbearing age will be CMV seropositive, depending on age, race, ethnicity, and geographic location.[78] Annual seroconversion rates among CMV-seronegative pregnant women vary between 1 to 7 percent, with an average of 2.3 percent.[210] The risk for intrauterine infection during pregnancy appears to vary with type of maternal infection.[260,269] Maternal CMV infection that is either primary or recurrent during pregnancy can result in an infant who is infected congenitally with CMV. However, the rate of intrauterine infection with recurrent infection in the mother is less than 1 percent, whereas transmission to the fetus occurs in 32 to 50 percent of mothers who are infected primarily with CMV during pregnancy.[230,412] Naturally occurring immunity to CMV infection reduces the risk for congenital CMV infection in future pregnancies by at least 69 percent.[161] Symptoms and sequelae are also much more likely to occur in infants congenitally infected as a result of the mother's primary infection during pregnancy than in infants congenitally infected from a recurrent maternal infection. However, even though symptoms are more likely in neonates congenitally infected as a result of a maternal primary infection, congenitally infected neonates from maternal recurrent CMV infections, resulting from reactivation of endogenous strain or reinfection with a new strain, may also experience long-term sequelae, including hearing loss and neurologic disease.[90]

Congenital Infection

Approximately 1 percent of all neonates are born congenitally infected with CMV; ranges of 0.18 to 2.5 percent are reported, varying between countries and the social demographics of the population.[230,269] There are an estimated 40,000 neonates with congenital CMV infection born annually in the United States.[41,84,374] Less than 20 percent (estimated 5% to 15% in most studies) of children with congenital CMV infection will show obvious clinical signs at birth, resulting in an estimated 8,000 to 10,000 children annually in the United States with long-term neurologic and sensory sequelae from congenital CMV disease. Although most neonates congenitally infected with CMV are asymptomatic, between 10 and 15 percent of apparently asymptomatic neonates have congenital hearing loss or may develop progressive sensorineural hearing loss.

*References 35, 121, 186, 209, 210, 302, 330, 331.

Perinatal Infection

CMV can be transmitted perinatally from a mother to her infant.[332] The virus can be shed in the CMV-seropositive mother's cervicovaginal secretions, urine, saliva, and breast milk. The most common and most efficient routes of perinatal transmission are ingestion or aspiration of cervicovaginal secretions at the time of delivery or ingestion of fresh breast milk after delivery. CMV-seropositive mothers, especially mothers with high levels of CMV IgG antibody, frequently shed CMV in their breast milk; and as many as 53 percent of children who are breast-fed with milk that contains infectious virus or CMV DNA can become infected with CMV.[138,220,312,446] These infections usually are benign in normal term infants but may be extremely serious in preterm, very low-birth-weight neonates.[274,445] In addition, as many as 57 percent of neonates whose mothers shed CMV at or around the time of delivery become infected with CMV.[359]

Postnatal Infection in Childhood

Children not congenitally or perinatally infected with CMV may be infected during the toddler or preschool years.[332] The acquisition of CMV by children between 1 and 3 years of age is influenced by home exposure to the virus, by the socioeconomic status or country of origin of the family, and by group daycare exposure.[77] Weller and Hanshaw[453] suggested that the child-rearing practices in Sweden, where group daycare was common practice, accounted for the relatively high prevalence of CMV infection in Swedish children compared with children in the United States and Great Britain, where daycare centers were not common at that time.

Pass and colleagues[318] first reported the prevalence of CMV in daycare centers in the United States in 1982. They found that 51 percent of children who attended a daycare center in Alabama excreted CMV in their saliva or urine. In this study, the prevalence of CMV excretion varied with age; 83 percent of children aged 13 to 24 months shed virus as opposed to only 9 percent of children younger than 1 year old. Pass and colleagues concluded that the high prevalence of CMV infection probably was due to horizontal spread between the children in daycare. Subsequent studies have confirmed a high prevalence of CMV excretion in children in daycare centers across the United States. Overall prevalence rates of 11 to 57 percent have been observed in many other studies in the United States and other countries, with the highest prevalence of active CMV infection (29% to 78%) found in children 1 to 3 years of age.[4,221,293,306,307] Child care homes may have lower prevalence of CMV excretion in children (8% to 15%); however, CMV seroconversion in home child care providers appears similar to that of child care providers in larger daycare centers.[36,318,320,321] Children who attend daycare centers also shed high titers of virus (up to 10^5 median tissue culture infective dose per milliliter), with a mean duration of viral shedding of 13 months in urine and 7 months in saliva.[292] This prolonged, generally asymptomatic shedding of large quantities of virus, coupled with mobility and the less than hygienic daily habits notorious in toddlers, no doubt facilitates the transmission of CMV in daycare centers.

Several studies support the idea that the high prevalence of CMV infection in young children who attend daycare centers is due to horizontal transmission; these studies used molecular fingerprinting techniques to show that infected children in contact with each other shed strains of CMV with similar or identical restriction enzyme banding patterns and that predominant strains of CMV appeared to circulate during a given period in a given daycare center.[4,5,208] Reinfection with a genetically different strain of CMV also has been observed and may be important in child-to-child transmission of CMV in the daycare center environment.[8] The importance of horizontal spread of CMV has been shown in special care centers for mentally retarded children as well.[390] CMV also has been isolated from plastic toys and from the hands of daycare center workers.[145,208,318]

CMV-infected children may transmit the virus to the daycare center workers who care for them.[5,7] In addition, children who attend daycare centers may transmit CMV to their CMV-seronegative parents. In one study of parents of children who attended one of three daycare centers in Alabama, 14 of 67 parents (21%) whose children attended daycare seroconverted, compared with none of 31 parents whose children were cared for at home.[322] Excretion of CMV by the child clearly was a key risk factor for parental seroconversion because none of the seroconversions occurred in parents whose children attended the daycare center but did not shed CMV. Moreover, this study revealed a strong trend toward a greater risk for acquiring CMV infection (seroconversion rate, 45%) in the parents of children 18 months or younger. Additional evidence implicating young children who attend daycare centers as a source of CMV infection for their parents was provided by a study in Virginia daycare centers, in which the parents of children in daycare shed CMV strains identical to the strains shed by their children.[6] Furthermore, CMV strains from daycare settings, when transmitted from toddlers to their pregnant mothers, may be the source of congenital infection.[293]

Whereas early childhood probably is the most rapid period of acquisition of CMV, annual seroconversion rates of only 3 to 6.2 percent have been observed in older children aged 3 to 10 years in the United States and other countries, thus reflecting an age-related plateau in the acquisition of CMV. One identified risk factor for the acquisition of CMV infection in a school-aged child has been recent or active CMV infection in a family member.*

Adolescents

In support of these early findings, a seroepidemiologic study of CMV infection in sexually active adolescent girls found a strong association between indicators of sexual activity and serologic evidence of CMV infection and concluded that sexual activity is an important risk factor

*References 102, 113, 129, 415, 416, 480.

for the acquisition of CMV infection in adolescent girls.[88,402] Early cross-sectional epidemiologic studies of CMV implied that a gradual increase in CMV antibody prevalence occurs during the teenage years, and this period of rapid acquisition was attributed to the intimate physical contact that commonly occurs during the teenage years.[17,367] However, these studies were conducted primarily in lower socioeconomic groups. In a seroepidemiologic study of several groups in Houston, Texas, on the acquisition of CMV infection in late childhood and adolescence, the prevalence of antibody increased with age in subjects of nonwhite races, as it did according to previous studies, but the prevalence of antibody in white subjects did not increase with age.[455]

Vertical transmission of CMV acquired during the teenage years may result in congenital infection with CMV in infants born to teenage mothers. In 1984, Kumar and colleagues[242] studied primary CMV infection in more than 3000 pregnant adolescents in Ohio. They found that 57 percent were CMV seropositive, that 1 percent of susceptible pregnant adolescents acquired CMV, and that the risk for intrauterine transmission was 50 percent if primary CMV infection occurred during pregnancy. Information provided by the National Congenital Cytomegalovirus Disease Registry and the National Center for Health Statistics suggests that adolescents who are pregnant actually may be at higher risk than are older mothers for giving birth to an infant with congenital CMV disease because 34 percent of mothers who give birth to an infant with congenital CMV disease are younger than 20 years old; however, this age group represents only 16 percent of the mothers giving birth in the United States.[115,212]

Intrafamilial Transmission

CMV also can be transmitted within the family setting. Evidence for intrafamilial transmission of CMV has been provided in the form of case reports, seroepidemiologic studies, and accounts in which molecular analysis of CMV strains was used to trace the transmission of CMV in family members or extended family members with temporally related CMV infections. In most studies, the index case was a child; when a CMV-infected child entered a household, attack rates were 47 to 53 percent.[427,433,474]

Three patterns of intrafamilial transmission have been observed: transmission between siblings, transmission between parents, and transmission between children and parents. Additional support for the intrafamilial transmission of CMV has been provided by published studies in which molecular analysis was performed on CMV isolates from family members or extended family members who experienced temporally related CMV infections. In each of these studies, restriction enzyme analysis of viral DNA from CMV isolates in family members showed that the strain of CMV was the same within each family.[136,323,410,474] New molecular techniques based on PCR amplification of a hypervariable region of the CMV genome also have corroborated the observation that genetically similar strains of CMV can be transmitted between family members over the course of time.[403]

Sexual Transmission

CMV also appears to be transmitted by heterosexual and homosexual contact. The evidence to support sexual transmission is anecdotal, virologic, serologic, and molecular and, taken together, suggests that sexual transmission of CMV is important in certain groups. However, because the virus is shed in saliva, cervicovaginal secretions, and semen, which form of intimate contact results in transmission between sex partners is unclear.[118,252,359]

Several observations support the idea that CMV can be transmitted sexually. For example, CMV antibody prevalence increases with age; CMV antibody is more prevalent in sexually active women than in celibate women; CMV antibody is associated with indices of sexual activity, such as recent infection with *Chlamydia trachomatis* or *Neisseria gonorrhoeae;* and a strikingly high annual incidence (37%) of primary CMV infection has been observed in young women with a recent first sexual experience.* In addition, in a longitudinal study of the site-specific shedding of CMV in human immunodeficiency virus (HIV)–seropositive homosexual and bisexual men, CMV was cultured from semen more frequently than from other body sites or fluids.[362] Moreover, molecular analysis of viral DNA has shown strains of CMV isolated from sex partners to be identical in most cases analyzed.[118,194]

Infection of the genital tract can recur by reactivation of an endogenous strain or by reinfection with an exogenous or different strain of CMV.[402] The consequences of such reinfections are unknown but may have important implications for transmission, especially if a CMV vaccine is used to control congenital CMV disease in the future. Sexual debut and recent sexual activity significantly influence CMV seroprevalence among women of childbearing age. In addition, engaging in sexual activity within 2 years of delivery of an infant adds increased risk for delivering a congenitally infected infant. Because sexual activity appears to influence CMV seroprevalence and congenital CMV infection rates, strategies to reduce sexual transmission of CMV may be important.[160,416]

Nosocomial Transmission

CMV can be transmitted in the hospital setting by transfusion of blood products, by bone marrow and organ transplantation, and, rarely, by person-to-person transmission. Despite numerous studies that have used serologic, virologic, and molecular epidemiologic techniques, transmission of CMV from a CMV-infected patient to a health care worker has not been documented.† Therefore, even though health care workers are exposed to CMV-infected patients, their risk for acquiring CMV appears to be no greater than that of the general population. In addition, unlike homes and daycare centers, hospitals routinely perform rigorous infection control procedures, including universal precautions, which probably accounts for the relatively low risk for acquiring CMV as well as other infections in the hospital setting.

*References 89, 101, 112, 160, 222, 402, 416, 461.
†References 9, 31, 37, 62, 120, 137, 206.

However, infant-to-infant transmission has been shown to occur, albeit infrequently, in crowded hospital units with a high prevalence of CMV excretion in patients.[120,406] CMV also can survive on plastic surfaces and has been cultured from inanimate objects in contact with CMV-infected patients in the hospital setting.[120,406]

Blood products are a well-established source of CMV infection, and donor-to-recipient transmission of CMV has been documented by restriction enzyme analysis of viral DNA.[432] Post-transfusion CMV mononucleosis can be seen in adults who receive large volumes of fresh whole blood.[224] In addition, 15 to 17 percent of CMV-seronegative neonates who receive blood products from CMV-seropositive donors acquire CMV.[474,475] Post-transfusion CMV infection in neonates, especially premature infants, can cause a syndrome of shock, lymphocytosis, and pneumonitis; CMV infection also appears to hasten the progression to bronchopulmonary dysplasia in these patients.[378,475]

CMV apparently is transmitted in the residual leukocytes found in whole blood, packed red blood cells, and platelet fractions as well as by pure leukocyte transfusions. The risk for development of post-transfusion CMV infection is approximately 3 percent per unit transfused, and the risk for symptomatic infection is much higher in CMV-seronegative recipients than in CMV-seropositive recipients.

Immunosuppressed Patients

Primary and reactivation infections as well as reinfection with CMV occur commonly in organ and marrow transplant recipients, as well as infants with primary immune deficiency syndromes that involve T-cell or natural killer (NK)-cell dysfunction or acquired immune deficiency from human immunodeficiency virus (HIV) infection or AIDS. The health care burden of severe CMV disease appears to be increasing in both these special patient groups.[387] Active infection with CMV occurs in almost all organ and marrow transplant recipients and usually is manifested clinically and virologically 30 to 90 days after transplantation. Rarely, CMV retinitis can occur years after a patient has undergone transplantation and generally is associated with chronic CMV viremia.[152] CMV can be transmitted to the recipient by the transplanted organ, by transfused blood products, and, theoretically, also by intimate contact with persons actively infected with CMV.

Infections with CMV are primary when they occur in CMV-seronegative recipients who receive transplants or blood products from CMV-seropositive donors. Recipients who are CMV seropositive before undergoing transplantation can experience reactivation of their own endogenous strain of CMV. In addition, CMV-seropositive transplant recipients may be superinfected by strains of CMV present in the donor organ.[94] In fact, in one study of renal transplant recipients in the United Kingdom, proven superinfection with the donor's strain of CMV occurred more frequently than did proven reactivation of the recipient's strain of virus.[188] Although reactivation, reinfection, and primary CMV infection all can produce symptoms in immunosuppressed transplant recipients, primary CMV infections are much more likely to be severe and even fatal.[340]

The type of transplant also appears to influence the type of CMV disease expressed. For example, the most severe and lethal form of CMV interstitial pneumonitis is seen in bone marrow transplant recipients, especially those experiencing a graft-versus-host reaction. CMV pneumonia also is a common occurrence after heart, lung, or renal transplantation, and severe CMV hepatitis is a special problem after liver transplantation.[16]

The iatrogenic immunosuppression essential for graft maintenance probably is responsible for the common occurrence of reactivation infection after transplantation, as well as the increased incidence of severe and symptomatic infection seen after primary CMV infection in transplant recipients. Cytotoxic drugs such as cyclophosphamide and azathioprine, in addition to corticosteroids, have been associated with reactivation of latent CMV infection, and the addition of antilymphocyte globulin to an immunosuppressive regimen can increase the morbidity of CMV infections.[324] The use of cyclosporine as the primary immunosuppressive agent, even in conjunction with corticosteroids, does not appear to reduce the risk for acquiring CMV infection compared with a regimen of azathioprine and corticosteroids; however, it may decrease the incidence of severe, symptomatic CMV disease in some transplant recipients.[135] The use of OKT3 to treat rejection in certain transplant patients increases the risk for dissemination in those with primary CMV infection.[393]

The frequency and morbidity of CMV infection in patients with malignant neoplasms are not as high as in patients who have undergone marrow and organ transplantation; however, the use of chemotherapy, especially for leukemia, is associated with significant CMV disease, particularly pneumonitis and persistent fever with viral dissemination. CMV-seropositive patients receiving immunosuppressive therapy for connective tissue disease also can have significant reactivation infection with CMV.[130]

The progressive and profound immunosuppression in adults and children with AIDS also is associated with CMV infection and disease. Although the source of CMV infection in adults with AIDS most likely is heterosexual or homosexual contact, sources of CMV infection in young children with AIDS have not been determined. One can hypothesize, however, that many of these infections are acquired from the mother, either congenitally or perinatally. Infants infected perinatally with HIV who also acquire CMV congenitally appear to be at significant risk for experiencing rapid progression of disease in the first 18 months of life, as well as debilitating neurologic disease.[131,241,386] Patients with AIDS also may be infected with multiple strains of CMV.[134,407]

Infants with primary immune deficiency syndromes involving T-cell or NK-cell function may have persistent CMV infection and progressive, life-threatening CMV disease. They often will have very high levels of CMV DNA levels by quantitative PCR in their blood or plasma, hepatosplenomegaly, pneumonitis, colitis, retinitis, thrombocytopenia, or elevated aminotransferase levels. Prompt diagnosis and management of possible

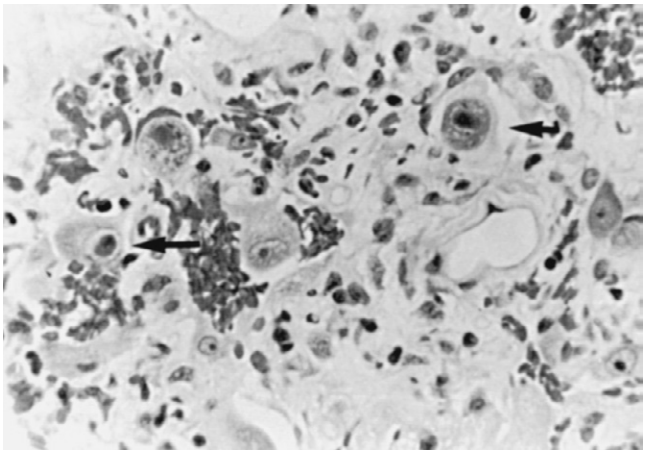

FIGURE 158-1 ■ Typical cytomegalic inclusion cells seen in lung tissue obtained by open-lung biopsy from a bone marrow transplant recipient with fatal cytomegalovirus pneumonitis (×640). (Courtesy Dr. Milton J. Finegold, Department of Pathology, Texas Children's Hospital, Houston.)

underlying immune disorder and specific antiviral therapy against CMV are important in these patients.

PATHOLOGY, PATHOGENESIS, AND IMMUNITY

CMV infection causes characteristic type A Cowdry intranuclear inclusions and massive enlargement of the affected cells (Fig. 158-1). It is this property of "cytomegaly" from which CMV acquired its name. The cytomegalic cells (25 to 40 μm in diameter) are two to four times larger than normal cells, and the nucleus usually is more than 10 μm in diameter. The intranuclear inclusion also is large (up to 10 μm in diameter) and is surrounded by an intranuclear halo and then the nuclear membrane, which gives a characteristic "owl's eye" appearance. Basophilic, granular, intracytoplasmic inclusions (2 to 4 μm in diameter) also may be present in cells that have intranuclear inclusions. These large cells represent productive virus infection, and both the nuclear and cytoplasmic inclusions contain viral nucleocapsids and express virus-specific antigens.[201] These cytomegalic cells frequently are associated with epithelial cells, and their presence generally indicates a productive and symptomatic infection with CMV. Cells also may be infected latently with CMV. These cells may express virus-specific antigen and contain viral nucleic acid without producing typical cytomegaly or a cytopathic effect. The significance of these cells must be considered carefully within the clinical context of the patient.

With severe, disseminated CMV disease, involvement can be seen in virtually all organ systems. The salivary glands frequently are infected in both symptomatic and asymptomatic infections, and the ductal epithelium usually is the site of pathologic involvement. The kidneys also are infected frequently in both symptomatic and asymptomatic CMV infection. In the kidneys, cytomegalic cells are most pronounced in the proximal tubules and interstitial cellular infiltrates, and even immune complex deposits can be seen in the glomeruli.

CMV infection often causes prolonged viruria, but it rarely results in significant renal dysfunction. In the lungs, cytomegalic cells are seen in alveolar and bronchial epithelium and are associated with mononuclear cell inflammation. Pulmonary alveolar macrophages also may express viral antigen and contain CMV DNA. The brain parenchyma can be involved, and a variety of pathologic processes can be observed and include sensorineural hearing loss. Other organs that can be infected or diseased with CMV include the liver, pancreas, adrenals, eyes, lymph nodes, heart, skin, bone, male and female genital tracts, esophagus, stomach, intestine, and placenta.

Infections with CMV can be latent and nonproductive, productive yet asymptomatic, or productive and symptomatic. Therefore, determination of whether a patient is "sick with CMV" or "sick from CMV" sometimes is difficult. Viral strain differences have not been shown to date to influence pathogenicity. However, immune responses, including maturity of the immune response, appear to be a major factor in virulence of the infection because CMV disease occurs more frequently in fetuses, premature neonates, transplant recipients, and patients with AIDS than in older healthy infants, children, and adults with acquired CMV infection.

The cell-mediated immune response, both specific and nonspecific, is thought to be important in host defense against CMV. The nonspecific immune mechanisms of NK cells and interferon production occur soon after the development of CMV infection, when early antigens are being produced and before infectious virus is released from the cell. The generation of cytotoxic T cells against CMV early antigens probably is the most important specific host immune response to CMV, and patients who are defective in this T-cell response are at high risk for acquiring serious CMV disease.[183]

Clinical and laboratory evidence also supports the concept of CMV as an immunosuppressive agent. The proliferative response of T cells to stimulation with mitogens and CMV antigen is suppressed in patients with CMV mononucleosis, and immunosuppressed patients with active CMV disease frequently have other opportunistic infections.[361] In addition, CMV pneumonitis in bone marrow transplant recipients has been hypothesized to result from host cell–mediated events produced in response to chronic viral replication.[483] Homology between certain CMV proteins and class I and class II major histocompatibility complex products has been observed. This "molecular mimicry" implies that the severe tissue destruction seen in CMV pneumonitis may be partly an autoimmune phenomenon in these patients.

Humoral immunity, on the other hand, does not appear to be a key factor in the host's defense against CMV infection. For example, the fetus can be infected by intrauterine transmission as a result of reactivation of CMV infection in a woman who is CMV seropositive before pregnancy, and infants frequently are infected perinatally from infected cervicovaginal secretions or breast milk in the presence of passive maternal antibody.[412] In addition, CMV-seropositive transplant

recipients can be reinfected with a new strain of CMV from the donor organ, and viruria and viremia occur in transplant recipients despite high titers of neutralizing antibody against the specific strain of CMV.[94,95] The presence of CMV antibody, therefore, should be considered a marker of previous or current infection with the virus rather than a measure of immunity per se.

Although humoral immunity does not appear to prevent infection with CMV, it does appear to lessen the severity of associated symptoms. Infants congenitally infected with CMV as a result of reactivation of infection in their mother almost always are asymptomatic, whereas perinatally infected infants rarely have significant symptoms. Primary infections in transplant recipients are more likely to be symptomatic than is reinfection or reactivation. One hypothesis regarding how CMV eludes host humoral defenses is that the virus binds to the host protein β_2-microglobulin and masks the antigenic determinants that are important for neutralization by antibody.[277]

CLINICAL MANIFESTATIONS

Fetal and Congenital Infections

The fetus with in utero CMV infection may show ultrasonographic abnormalities, including signs of abnormal somatic or head growth, enlarged liver or spleen, echogenic bowel patterns, and hepatic calcifications, as well as biologic findings such as fetal thrombocytopenia and lymphopenia and elevated liver enzymes and elevated CMV-specific IgM antibody levels. In addition, cerebral fetal ultrasonography may show enlarged ventricles in the fetal brain, intracranial calcifications, or microcephaly or mimic a Dandy-Walker malformation in severe cases.[29,190,263] Annually, 30,000 to 40,000 infants are born with congenital CMV infection. Of these infants, as many as 10 percent have severe, classic "cytomegalic inclusion disease," characterized by intrauterine growth retardation, jaundice, hepatosplenomegaly, thrombocytopenia with petechiae and purpura, pneumonia, and severe central nervous system (CNS) damage with microcephaly, intracerebral calcifications, chorioretinitis, and sensorineural hearing loss. Another 5 percent have atypical involvement, such as ventriculomegaly, periventricular leukomalacia, periventricular cystic malformations with or without calcifications, polymicrogyria, cerebral thrombosis, strabismus, optic atrophy, long bone osteitis characterized by fine vertical metaphyseal striations, isolated and transient thrombocytopenia and petechiae, cutaneous vasculitis, hemolytic anemia, ascites, chronic hepatitis, and intrahepatic cholestatic disease.* As many as 90 percent of these infants who are symptomatic at birth later have neurologic sequelae, vision loss, or progressive deafness. However, the range of severity of these sequelae appears to be broad, and severity may be predicted by head circumference and computed tomographic (CT) findings at birth.[57,304] In addition, CMV viremia and high levels of CMV DNA by PCR analysis in the blood or plasma in congenitally infected neonates is associated with symptomatic disease and hearing loss at birth, suggesting that the level of virus contributes to disease severity.[56,61]

The differential diagnosis of symptomatic congenital CMV disease includes congenital toxoplasmosis, congenital HSV infection, congenital syphilis, congenital rubella syndrome, congenital infection with lymphocytic choriomeningitis virus, and congenital HIV infection. In addition, noninfectious causes, such as genetic disorders, metabolic disease, and maternal exposure to drugs and toxins, should be considered.

Most infants who are infected congenitally with CMV are asymptomatic at birth. However, 10 to 17 percent of these infants later may have unilateral or bilateral deafness or differences in higher-level auditory function.[103,412,460] Progressive or late-onset hearing loss also may occur in these infants, thus rendering it likely that universal neonatal hearing screening programs will miss rather than detect many of these children.[158,305] Small retinal lesions may occur as well.[99] Earlier studies suggested that developmental problems may occur in asymptomatically infected children, but more recent studies suggest that cognitive outcome appears to be normal compared with uninfected children.[228]

Very low-birth-weight infants who are infected congenitally with CMV may experience pulmonary and systemic deterioration temporally associated with corticosteroid therapy.[436]

Neonates and young infants younger than 6 months of age with persistently high levels of CMV viremia or high levels of CMV DNA by PCR analysis in the blood or plasma, or infants who have significant rebound of their CMV DNA levels after antiviral treatment, may have a primary immune disorder of T-cell function, such as severe combined immune deficiency, or a disorder of NK-cell function. Prompt diagnosis and management of their underlying immune disorder, as well as specific antiviral therapy against CMV, are important in these patients.

Perinatal Infections

Perinatally acquired infections in healthy infants usually manifest when the child is between 4 and 16 weeks of age, but most such infections are asymptomatic. However, as many as one third of infants exposed to CMV perinatally may have signs and symptoms of disease associated with CMV infection, most often self-limited lymphadenopathy, hepatosplenomegaly, hepatitis, or pneumonitis.[244] Perinatally acquired infection with CMV also can cause a viral, sepsis-like syndrome or severe, protracted pneumonitis that has been associated with the development of bronchopulmonary dysplasia in premature infants.[274,378] A limited number of studies suggests that these infections, however, do not appear to cause neurodevelopmental sequelae or deafness.[245] Infants with primary immune deficiency of T-cell or NK-cell function, or AIDS from perinatally acquired HIV infection, who acquire CMV perinatally may have CMV viremia, high levels of CMV DNA by PCR analysis in blood or plasma, and associated hepatosplenomegaly, thrombocytopenia, viral sepsis, pneumonia, retinitis, or colitis.

*References 18, 27, 99, 155, 218, 306.

Prompt diagnosis of an underlying primary immune disorder, as well as antiviral therapy, is lifesaving management in these patients. The differential diagnosis includes other perinatally acquired infections, such as *Chlamydia* pneumonitis, hepatitis B virus infection, and infection with HIV, as well as postnatally acquired infections with enteroviruses, adenovirus, and a variety of bacterial pathogens.

Mononucleosis Syndrome

CMV-induced mononucleosis occurs as a primary infection in both immunocompetent and immunosuppressed persons, in pregnant women, and, occasionally, as a reactivation infection in immunosuppressed patients.[260] It can result from person-to-person transmission of the virus as well as from transmission by blood products or by organ or marrow transplantation. Although originally described in adults and most often occurring in patients between 20 and 40 years of age, it also can be seen in adolescents, children, and even infants.[268,316] Typical CMV-induced mononucleosis is characterized by fever and strikingly severe malaise of 1 to 4 weeks' duration, peripheral lymphocytosis with atypical lymphocytes, and mildly elevated liver enzymes. In some patients, headache, myalgias, and abdominal pain with diarrhea are prominent symptoms. In premature infants with transfusion-acquired CMV mononucleosis, prominent manifestations include shock, hepatosplenomegaly, pneumonitis, thrombocytopenia, and renal failure.[406] In contrast to Epstein-Barr virus–induced mononucleosis, CMV-induced mononucleosis rarely causes pharyngitis, tonsillitis, or significant splenomegaly, and it does not result in production of heterophil antibodies.[100,207] However, like Epstein-Barr virus–induced mononucleosis, it can be associated with morbilliform rash after administration of ampicillin, elevated erythrocyte sedimentation rate, polyclonal hypergammaglobulinemia, and production of other antibodies such as rheumatoid factor, cold agglutinins, and antinuclear antibodies. Complications rarely occur but include interstitial pneumonitis, myocarditis, pericarditis, hemolytic anemia, thrombocytopenia with or without petechiae or purpura, hemophagocytic syndrome, arthralgias and arthritis, maculopapular rashes, adrenal insufficiency, splenic infarction, ulcerative colitis and proctitis, Guillain-Barré syndrome, and meningoencephalitis.* Severe, icteric hepatitis as well as granulomatous hepatitis also can occur, but hepatic necrosis and liver failure caused by CMV have not been documented convincingly in normal hosts.[54,100,207,240,356]

The differential diagnosis of CMV-induced mononucleosis includes mononucleosis induced by other viruses such as Epstein-Barr virus, hepatitis A or B virus, and HIV. In addition, acquired toxoplasmosis can produce a mononucleosis syndrome in healthy persons.

Interstitial Pneumonitis

CMV is a major cause of interstitial pneumonia in both adults and children who are immunosuppressed because of congenital primary immunodeficiency of T-cell or NK-cell function, AIDS, organ or marrow transplantation, or malignant disease. In recipients of bone marrow transplants, CMV accounts for 17 to 70 percent of cases of interstitial pneumonitis in adult patients but only 10 percent of cases in patients younger than 21 years.[452,453] Pneumonia also can occur in apparently immunocompetent young infants with perinatally acquired CMV infection and in healthy adults with CMV-induced mononucleosis.[233,244,411,457] Whereas the pneumonia in immunocompetent hosts almost always is benign and self-limited, CMV pneumonia in immunosuppressed patients is a serious, often fatal illness, especially in bone marrow transplant recipients, who have a mortality rate of up to 90 percent. It also can be particularly troublesome after pediatric heart and lung transplantation.[303] CMV pneumonitis usually occurs 1 to 3 months after the patient has undergone transplantation and begins with symptoms of fever and a dry, nonproductive cough. It then can progress during the course of 1 to 2 weeks to dyspnea, retractions, wheezing, and hypoxia, which require ventilatory support. It may occur as the only disease manifestation or be part of a disseminated CMV infection. The radiographic appearance of CMV pneumonia usually is diffuse, interstitial infiltrates, but peribronchial infiltrates with hyperinflation and nodular pulmonary infiltrates also have been described (Fig. 158-2).[233,429] Coinfection with other pathogens, especially gram-negative enteric bacteria and fungal pathogens in transplant recipients and in patients with *Pneumocystis jiroveci* infection and AIDS, can occur.[448]

Congenitally infected infants also may be born with CMV pneumonitis, which often is sufficiently severe to require ventilatory support and usually is part of a multisystemic CMV disease process. Very low-birth-weight

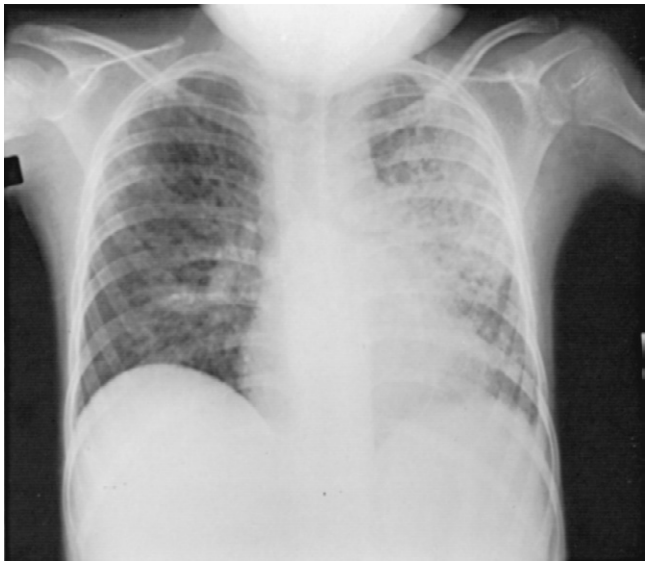

FIGURE 158-2 ■ Chest radiograph of a bone marrow transplant recipient with rapidly fatal cytomegalovirus pneumonitis. An open-lung biopsy specimen showed numerous cytomegalic inclusion cells, exhibited cytomegalovirus early antigens by immunoperoxidase staining, and grew cytomegalovirus after inoculation into tissue culture.

*References 87, 100, 109, 151, 207, 239, 240, 259.

infants who are infected congenitally with CMV may experience CMV pneumonitis in temporal association with corticosteroid therapy.[436]

The differential diagnosis of CMV pneumonitis in immunocompromised patients, including neonates, is extensive. It includes infection with other viruses, such as HSV, VZV, measles virus, respiratory syncytial virus, influenza A and B viruses, parainfluenza viruses, and adenoviruses; bacterial pneumonia caused by a variety of gram-positive and gram-negative organisms; infection with protozoa, such as *P. jiroveci* and *Toxoplasma gondii;* infection with *Chlamydia* and *Mycoplasma;* and fungal pneumonia, caused especially by *Candida* and *Aspergillus.* Noninfectious causes of pneumonitis, such as pulmonary hemorrhage, aspiration pneumonia, rejection, and pulmonary damage from chemotherapeutic agents, also should be considered.

Retinitis and Other Eye Abnormalities

Chorioretinitis as well as optic atrophy, cortical blindness, and strabismus occur in 17 to 41 percent of neonates with symptomatic congenital CMV infection and rarely in children born with asymptomatic congenital CMV infection.[55,99,374] Although most retinal lesions in congenitally infected infants appear to be inactive at birth, some observations suggest that progression of preexisting lesions and late-onset new lesions resulting in vision loss may occur rarely in both symptomatic and asymptomatic congenitally infected infants.[55,104] Retinitis does not seem to be a prominent part of perinatally or early postnatally acquired infection in immunologically normal infants but has been rarely reported to occur.[245,329] Infants with primary immune disorders involving T-cell or NK-cell dysfunction, on the other hand, often have CMV viremia, usually at persistently high titers, and CMV retinitis. CMV retinitis once was a rare manifestation of CMV disease in solid-organ transplant recipients undergoing chronic immunosuppression for more than a year and in patients receiving chemotherapy for malignant disease.[152] In the 1980s, CMV retinitis emerged as a frequent manifestation of CMV disease in patients with severe immunosuppression, especially bone marrow transplant recipients and patients with AIDS. It probably is a result of hematogenous spread of the virus to the retina, with continued local viral replication. Despite the common occurrence of CMV retinitis in adults with AIDS, however, it rarely has been reported in children with AIDS.[261]

CMV produces characteristic white, perivascular infiltrates and hemorrhage, with a necrotic, rapidly progressive retinitis. It descriptively has been called "cottage cheese" retinitis and "ketchup" or "brushfire" retinitis.[52] Early, peripheral retinitis can be asymptomatic, or the complaints may be minimal and nonspecific; it is especially difficult to ascertain in infants and young children. It does not cause eye pain, photophobia, or conjunctivitis. Once the retinitis has progressed, it can cause blurred vision, decreased visual acuity, visual field defects, and blindness. Young children and infants who have suffered visual loss as a result of CMV retinitis may exhibit strabismus or failure to fix and follow objects within their visual field. CMV retinitis also can progress rapidly to total blindness if the macula is involved. Immunosuppressed children from any cause who have CMV disease or persistently high levels of CMV DNA in their blood or plasma should receive regular expert ophthalmologic examinations to monitor for the development of sight-threatening retinitis. Establishing the diagnosis early may allow prompt institution of antiviral therapy, which may be sight saving.[261]

The ophthalmoscopic appearance of CMV retinitis usually is characteristic. However, in patients in whom the appearance of the retina is not typical or in whom the retinitis has progressed despite specific antiviral treatment, other causes of retinal lesions that should be considered include cotton-wool spots associated with hypertension, diabetes, connective tissue disease, anemia and leukemia, ocular toxoplasmosis, and candidal infection of the retina as well as syphilis, HSV infection, lymphocytic choriomeningitis virus infection, and VZV infection. Detection of the virus by culture or its DNA by a PCR-based method in vitreous fluid may help establish the diagnosis in difficult or atypical patients.[149] CMV antibodies also have been detected in the tears of patients with active ocular infections, including retinitis.[373]

CMV also has been associated in some studies with other unusual eye abnormalities. In coincidentally congenitally infected infants, microphthalmos, anophthalmia, optic nerve hypoplasia and coloboma, optic nerve atrophy, Peter anomaly, and irregular retinal pigment have been observed.[164] However, the role that CMV is playing in these anomalies is unclear and unsubstantiated by prospective studies.[99] CMV also does not appear to cause congenital cataracts.[392] CMV also has been isolated from tears and has been associated with conjunctivitis in patients with CMV mononucleosis and AIDS as well as with corneal epithelial keratitis and disk neovascularization.[256]

Hepatitis

CMV hepatitis in neonates with congenital CMV disease, in children who are bone marrow, heart, and lung transplant recipients, in patients with cancer or AIDS, in infants with primary immune deficiency of T-cell or NK-cell function, and even in healthy persons experiencing a primary CMV infection usually is manifested as mild to moderate hepatomegaly and mildly to moderately elevated serum hepatic enzyme levels. Infants with primary immune disorders of T-cell and NK-cell function may have progressive hepatomegaly and increasing aminotransferase levels and the presence of CMV evident on histopathology in the liver. CMV hepatitis commonly occurs in conjunction with fever, thrombocytopenia, and lymphopenia or lymphocytosis. Jaundice and hyperbilirubinemia may occur, severe hepatitis or cirrhosis is exceedingly rare, and hepatic necrosis and liver failure caused by CMV hepatitis have not been documented convincingly in these patients. CMV infection also has been associated with granulomatous hepatitis.[54,356] In addition, CMV hepatitis is a unique and prominent problem in children who have undergone liver transplantation.[64] Most CMV hepatitis occurs 1 to 2 months after

the patient has undergone transplantation, but it may be noted as early as 2 weeks or as long as 4 months afterward.[66] It is more common and more severe after a primary CMV infection and is associated with liver transplantation from a CMV-seropositive donor and the use of OKT3 antibodies for severe rejection.[394] CMV hepatitis in liver transplant recipients is characterized by prolonged fever, leukopenia, thrombocytopenia, elevated levels of liver enzymes, hyperbilirubinemia, and liver failure. Distinguishing between CMV hepatitis and acute rejection often is difficult, even with a liver biopsy, and the two commonly coexist. CMV infection also has been associated with ascending cholangitis, chronic rejection, and the vanishing bile duct syndrome in liver transplant recipients.[66,308]

Infants with congenital CMV disease also may have hepatitis. The liver usually is smooth and nontender and commonly extends 3 to 5 cm below the right costal margin. Ascites may be present prenatally and may persist postnatally for 1 to 2 weeks. The hepatomegaly usually resolves by the time the infant is 3 months of age, and persistence beyond 1 year is highly unusual. Mild hepatitis generally is present, and aminotransferase levels in neonatal hepatitis caused by CMV rarely exceed 500 IU. Hyperbilirubinemia is present at birth in approximately a third of neonates with congenital CMV and may be striking, with conjugated (direct) bilirubin levels up to 30 mg/dL.[212] The abnormal results of liver function tests gradually resolve during the course of the first few weeks of life, and chronic hepatitis as a result of congenital infection with CMV is an unusual occurrence. Congenital CMV disease also has been associated with intrahepatic and extrahepatic biliary atresia in some studies, but the direct role of CMV in neonatal cholestatic disease is unclear.[18,155,218] A neonate or infant with congenital CMV disease and recurrent, persistent or progressive hepatomegaly and hepatitis, despite antiviral treatment, may have an underlying primary immune deficiency of NK-cell or T-cell function.

The differential diagnosis of CMV hepatitis includes other causes of viral hepatitis, such as hepatitis A virus, hepatitis B virus, hepatitis C virus, Epstein-Barr virus, HSV, enterovirus, and adenovirus as well as toxoplasmosis; other infections, such as bacterial ascending cholangitis; and noninfectious causes, such as ischemic injury, vascular thrombosis, hemolysis, rejection, and hepatitis induced by drugs or toxins. In neonates with a significant and persistent direct hyperbilirubinemia, the diagnosis of biliary atresia should be considered as well.

Gastrointestinal Disease

Serious gastrointestinal disease causing esophagitis, gastritis, gastric outlet obstruction, gastroenteritis, pyloric and small bowel obstruction, duodenitis, colitis, proctitis, pancreatitis, hemorrhage, and acalculous cholecystitis has been associated with CMV infection in immunocompromised persons, especially patients with AIDS or neoplastic disorders and those who have undergone bone marrow, kidney, intestinal, or liver transplantation.* Rarely, self-limited CMV gastroenteritis, colitis, and proctitis have been associated with CMV mononucleosis syndrome in apparently normal individuals.* CMV enterocolitis has also been reported as a cause of intractable diarrhea, that often is bloody, in infants with congenital and postnatal CMV disease.† Characteristic signs and symptoms in infants and children include nausea, vomiting, dysphagia, epigastric pain and tenderness, delayed gastric emptying, watery guaiac-positive stools or gastrointestinal hemorrhage, and disaccharide and monosaccharide intolerance.[275,286,440] Severe disease may cause dehydration and failure to thrive. Endoscopy with biopsy is required to establish a definitive diagnosis and usually shows linear, localized, or punctate ulcers. Hemorrhagic lesions or diffuse erosion can occur in severe disease. Characteristic cytomegalic inclusion cells can be seen in the gastrointestinal endothelium, epithelium, and glandular tissue; CMV may be cultured from stool or biopsy specimens; or CMV DNA may be detected by PCR-based methods.[174] In addition, these patients often are viremic with CMV DNA by PCR detectable in their blood or plasma and occasionally have evidence of disseminated CMV infection with involvement of the lungs and retina. Infants with severe end organ disease caused by CMV should receive an immunologic workup to exclude primary immune deficiency of T-cell or NK-cell function.

The differential diagnosis of CMV colitis includes infection with other viruses, especially HSV and adenovirus, and infection with bacteria, particularly *Salmonella*, *Shigella*, *Campylobacter*, and *Yersinia*, as well as *Clostridium difficile* and *Mycobacterium avium-intracellulare*. Parasitic infection with *Cryptosporidium*, *Giardia*, and amebae also should be excluded. The differential diagnosis of CMV esophagitis and gastritis includes HSV infection, *Candida* esophagitis, reflux esophagitis, and peptic ulcer disease.

Meningoencephalitis and Other Neurologic Disorders

CNS involvement is well described and occurs relatively frequently in infants with symptomatic congenital CMV infection. Although the severity of damage to the CNS during congenital infection varies greatly, postmortem examination of severely affected infants has demonstrated necrotizing encephalitis, especially in the deep periventricular structures, and scattered areas of necrosis and inclusion-bearing cells. Although direct viral infection of neural structures probably plays a major role in CNS disease in congenital CMV infection, infectious vasculitis also may occur. In addition, because congenital CMV disease can be associated with marked thrombocytopenia, intracranial hemorrhage can contribute to CMV-related CNS injury.[34,73,196,443] Clinical manifestations of this disease process include microcephaly, cerebral palsy, intracerebral calcifications, seizures, hemiparesis, developmental delay, ventriculomegaly, paraventricular cysts, intraventricular strands, periventricular leukomalacia, lissencephaly-pachygyria, porencephaly, schizencephaly, cortical malformations such as

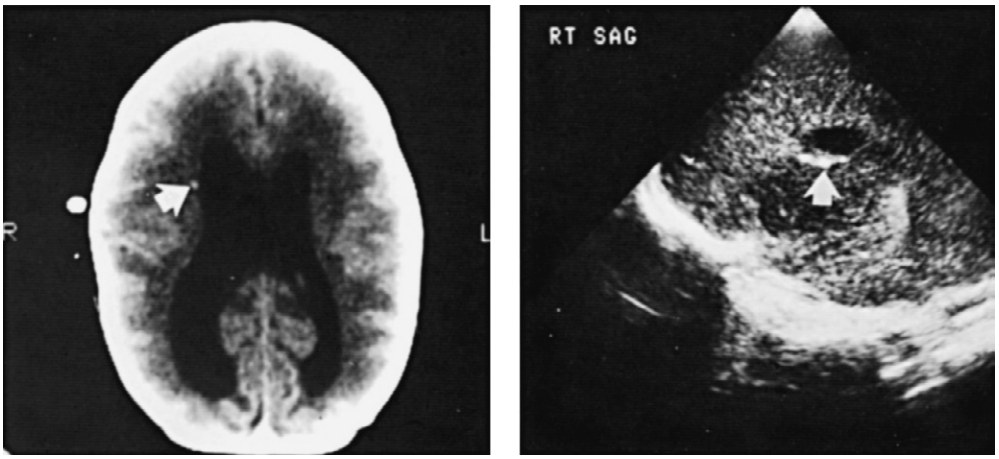

FIGURE 158-3 ■ CT scan *(left)* and ultrasound examination *(right)* of the head of an infant with congenital cytomegalovirus disease. Both tests showed moderate asymmetric enlargement of the lateral ventricles with punctate periventricular calcifications.

polymicrogyria, multifocal deep white matter lesions and gliosis, atrophy from cerebral volume loss, parenchymal and ependymal cysts, periventricular cysts, cerebellar lesions, meningoencephalitis, and sensorineural deafness (Fig. 158-3).[90,247,306,425,438] Remarkably, despite the well-documented neuropathologic process in congenital disease, isolation of CMV from the cerebrospinal fluid (CSF) of a congenitally infected child is an extremely unusual finding.[216] CMV DNA has been detected in the CSF of congenitally infected infants, and its presence at birth appeared to identify infants at risk for a poor neurodevelopmental outcome.[26]

The differential diagnosis of symptomatic congenital CMV infection with neurologic disease includes congenital toxoplasmosis, congenital HSV infection, congenital rubella syndrome, congenital infection with lymphocytic choriomeningitis virus, brain tumors such as craniopharyngioma, and calcified hematoma. In addition, congenital CMV disease involving the CNS also may be mimicked by genetic disorders such as tuberous sclerosis, Sturge-Weber syndrome, and Aicardi syndrome; metabolic conditions such as hyperthyroidism; α_1-antitrypsin deficiency; galactosemia; peroxisome disorders such as Zellweger syndrome, neonatal adrenoleukodystrophy, and infantile Refsum disease; urea cycle deficiencies; organic acidemias; and liposomal storage disorders.[33] Maternal exposure to drugs and toxins, especially isotretinoin, cocaine, and alcohol, also is included in the differential diagnosis. The presence or absence of intracerebral calcification as well as the pattern of calcifications when they are present may be helpful in distinguishing among these disorders. In addition, the appropriate microbiologic studies, chromosome analysis, metabolic studies, and drug screens should be performed.

In postnatal life, CMV meningoencephalitis appears to be rare yet well documented.[32] It may occur as a complication of CMV mononucleosis, as an isolated manifestation of primary CMV infection in a normal host, or as a primary or recurrent infection in an immunocompromised patient.[345] In infants, it may be the presenting condition of a primary immune deficiency of T-cell or NK-cell function. Symptoms include headache, photophobia, nuchal rigidity, memory deficits, and inability to concentrate. CSF findings include mild mononuclear pleocytosis and slightly elevated protein. Although the virus is isolated from the CSF and brain parenchyma exceedingly rarely, neuropathologic findings of intranuclear inclusions and microglial nodules are characteristic.

CMV encephalitis may complicate adult and pediatric immunocompromised transplant recipients and patients with AIDS.[39] As many as 50 percent of patients with AIDS may have evidence of CMV infection of the CNS at postmortem examination.[296] CMV has been reported to cause a subacute, occasionally progressive encephalitis in patients with AIDS and has been implicated as a cofactor in the pathogenesis of the AIDS dementia complex seen in both adults and children.[108,200,287,397,459] In this disease, CMV may be isolated from CSF or CMV DNA may be detected in the fluid or brain by PCR-based methods.[177] In children, this syndrome is characterized by weakness, confusion, and loss of developmental milestones.

The differential diagnosis of CMV encephalitis and meningoencephalitis in a normal host includes primarily infection with other neurotropic viruses, such as HSV, Epstein-Barr virus, VZV, enterovirus, and arboviruses. Neurosyphilis and tuberculous meningitis also should be considered. In immunocompromised patients, especially those with AIDS, the following should be added to the differential diagnosis of CNS infection: progressive multifocal leukoencephalopathy caused by papovavirus; HIV encephalitis; fungal CNS infection caused by *Cryptococcus neoformans*, *Candida* spp., *Aspergillus*, or *Histoplasma;* protozoal infections with *T. gondii* and, rarely, *P. jiroveci* and *Strongyloides stercoralis;* bacterial infections with *M. avium-intracellulare* and *Nocardia asteroides;* noninfectious diseases such as primary cerebral lymphoma and lymphomatoid granulomatosis; and vascular complications such as hemorrhage and infarction.[20] In immunosuppressed patients, more than one of these conditions can coexist in the CNS.

CMV also can invade the peripheral nervous system and cause a painful peripheral neuropathy in patients with AIDS.[166,365,442] Ascending paralysis caused by myelitis, with or without vasculitis or necrosis, also can occur

and may appear similar to Guillain-Barré syndrome.[442] In addition, CMV polyradiculopathy has been described in adult patients with AIDS and may occur in older children. This disease usually begins as leg pain and sacral paresthesias and may progress to weakness and flaccid paralysis. The CSF characteristically has a polymorphonuclear pleocytosis and moderately elevated protein level.[234] The association of CMV infection with infantile spasms, Guillain-Barré syndrome, Charcot-Marie-Tooth disease, Huntington disease, Alzheimer disease, myasthenia gravis, and neuropsychiatric diseases (e.g., schizophrenia) has been reported, but a definite causal relationship between CMV and these diseases remains to be proved.[32,238]

Deafness and Other Ear Disorders

Hearing loss is present at birth in 25 to 50 percent of infants with symptomatic congenital CMV infection and in approximately 15 percent of infants with asymptomatic congenital CMV infection.[212] Given that congenital CMV infection affects 30,000 to 40,000 infants annually in the United States, this congenital infection probably is the most common cause of nonhereditary sensorineural deafness. Investigators have estimated that congenital CMV infection may account for as many as 40 percent of cases of congenital hearing loss.[40,127,187] Progression or fluctuation of the hearing loss occurs in at least two thirds of these children through the preschool years, and continued progression may occur through the school-age and adolescent years.[159,460] Although CMV has been detected in the endolabyrinth of infants who died of congenital CMV disease, whether this progressive deafness is caused by continued viral replication in the inner ear, reinfection with a new strain of virus, or a complex cascade of immunopathologic events remains unclear.[111] Mondini dysplasia of the temporal bones has been seen in infants with congenital CMV infection, but the importance of this observation relative to the pathogenesis of the progressive hearing loss commonly seen in congenitally infected infants is unknown at this time.[47] Some studies suggest that higher levels of CMV in urine and blood are present in neonates who develop hearing loss from congenital CMV infection,[22,251,364,447] whereas other studies speculate that genetic mutations or inflammatory genes may play a role in CMV-associated hearing loss.[305,309,370,385]

CMV has been isolated from the middle ear effusions of healthy and immunocompromised children with otitis media.[93,141] In addition, CMV infection, defined serologically, has been associated with sudden-onset deafness, acute labyrinthitis, and Meniere syndrome.[420,462,463] Older children who were born with asymptomatic congenital CMV infection also may exhibit differences in higher auditory function, even though they do not have sensorineural or conductive hearing loss.[103]

Myocarditis and Other Cardiovascular Disorders

Myocarditis has been described as a rare complication of severe congenital CMV disease and CMV mononucleosis in presumably otherwise healthy adults and children.[431,450,463] CMV myocarditis also has been seen in renal and heart transplant recipients, usually as part of a disseminated CMV infection and associated with graft rejection treated with high-dose immunosuppressive therapy.[173,341,388] Myocarditis caused by CMV may be present in infants with primary immune deficiency disorders of T-cell and NK-cell function. Patients can have heart failure, cardiomegaly, electrocardiographic abnormalities, and poor left ventricular function on echocardiography; cytomegalic inclusion cells and the presence of CMV DNA can be documented by myocardial biopsy.

The association of CMV infection with other cardiac disorders such as congenital heart block, structural cardiac anomalies, and pericarditis is anecdotal, and a cause-and-effect relationship is not well documented.[227]

Thrombotic phenomena, often serious and life threatening, have been associated with primary and active CMV infection in neonates, infants, adolescents, and adults, as well as transplant recipients and patients with HIV infection/AIDS.[2,114,266] The virus may cause damage to endothelial cells, activate coagulation factors, and induce production of antiphospholipid antibodies.[405]

CMV coronary endotheliitis with superimposed thrombosis and myocardial infarction has been described in adult heart transplant recipients and was reported in an infant who died of disseminated CMV disease with an apical ventricular aneurysm.[285,376] CMV primary or acute infection also has been associated with venous and arterial thrombosis in previously healthy individuals, in patients undergoing solid-organ transplant (especially renal and heart transplant recipients), and in infants with congenital and early postnatal CMV infection.[1,27,266] Primary CMV infection has been associated with pulmonary embolism and portal vein thrombosis in an adolescent with CMV mononucleosis.[1-3,250] CMV infection has been postulated to play a role in the pathogenesis of atherosclerosis and coronary artery disease in animal models, as well as in both normal persons and heart transplant recipients.[179,219,276,279,429] High levels of CMV antibody have also been epidemiologically associated with coronary artery disease in studies in performed in many countries and continents, including India, Finland, the United States, and China.*

CMV also has been associated with hypertension in animal (murine) models, but studies definitely linking CMV to hypertension in humans have not been definitive.[92]

Endocrine System

Histopathologic evidence of involvement of the organs of the endocrine system is described well in both congenital and postnatally acquired disseminated CMV infections.[201] Endocrine disorders such as Graves disease and diabetes insipidus have been associated with congenital CMV infection, but these reports may represent coincidental findings.[280,375] Longitudinal studies are required to determine whether the autoimmune endocrinopathies in children with congenital rubella parallel the findings

*References 1-3, 219, 290, 291, 405.

in children with congenital CMV infection. CMV infection also has been associated with autoimmune type 1 diabetes, although a specific cause-and-effect relationship has not been established.[315] In addition, immunosuppressed patients, especially persons with AIDS, may manifest clinical endocrinopathies caused by CMV infection, such as adrenal insufficiency and adrenal necrosis.[180] CMV inclusions also have been found in the pituitary gland of patients with AIDS, all of whom showed evidence of CMV encephalitis or disseminated infection elsewhere in the body.[150] Moreover, involvement of the thyroid and parathyroid glands with CMV has been reported in adults with AIDS.[163]

Genitourinary System

Disease of the male and female genitourinary system as a result of CMV has been reported. Patients with AIDS may have symptomatic epididymitis and cystitis caused by CMV.[49,347,422] Lower urinary tract infections and hemorrhagic cystitis caused by CMV have been diagnosed in patients after they have undergone stem cell and solid-organ transplantation.[314] CMV also commonly yet asymptomatically infects the cervicovaginal secretions and semen of both healthy and immunosuppressed adults.[222,252]

Skin

Cutaneous manifestations of CMV infection are described well and can occur with both congenital and acquired CMV infection.[259] Infants with symptomatic congenital infection may have nonpalpable petechiae, purpura, or bruises, usually as a result of thrombocytopenia. Violaceous or dark, magenta infiltrative papules or nodules, called "blueberry muffin" lesions, also may occur, but these lesions are more characteristic of congenital rubella syndrome. The skin lesions associated with acquired CMV infection usually are localized cutaneous ulcers or a widespread, exanthematous, maculopapular eruption, although vesiculobullous lesions also have been described.[326] CMV mononucleosis syndrome in adults and children may be accompanied by a maculopapular, rubelliform rash that may be pruritic. In addition, ampicillin-associated rashes may occur with CMV mononucleosis. CMV also may cause a cutaneous, leukoblastic vasculitis.[377] Well-demarcated, ulcerated lesions that show histopathologic evidence of CMV infection may be seen in immunocompromised patients who have undergone transplantation or in those who suffer from AIDS. Finally, CMV may play a cofactor role with human herpesvirus type 8 in the neoplastic process in Kaposi sarcoma, but definitive proof of a causal relationship remains to be shown.

Unusual Associations

CMV infection, either congenital or acquired, has been detected in association with a wide variety of conditions, including defects in tooth structure and the formation of enamel, arterial or venous thrombosis, atherosclerosis, portal vein thrombosis associated with protein S and protein C deficiency, unexplained fevers in burn patients, bacterial sepsis in burn patients, congenital eventration of the diaphragm, inguinal hernia, and fatal *Staphylococcus epidermidis* infection in very low-birth-weight infants.* CMV infection also may be involved in the genesis and maintenance of immunopathologic phenomena, such as allograft rejection in solid-organ transplant recipients and graft-versus-host disease in bone marrow and stem cell transplant recipients, as well as autoimmune diseases.[246,438] Case reports have linked primary CMV infection with the onset of autoimmune disorders or recurrent CMV infection with worsening of autoimmune disease.[192,328,439] CMV also has been associated with hemophagocytic syndrome in adults and children.[246] However, given the common occurrence of CMV infection, it is difficult to determine if the relationships are coincidental or comorbid, rather than part of a cause-and-effect relationship.

LABORATORY DIAGNOSIS

Detection of the Infectious Agent

CMV can be isolated in cell culture with fibroblast cell lines such as human foreskin fibroblasts and human embryonic lung fibroblasts.[384] Specimens that contain a high titer of virus, such as those from congenitally infected infants, may show growth in 24 hours. Some specimens, such as those from persons with acquired asymptomatic infection, may require as long as 6 weeks for detectable growth, but most cultures grow in 1 to 2 weeks. CMV has been isolated from a variety of specimens, including urine, saliva, nasopharyngeal and sinus washings, conjunctiva, tears, middle ear fluid, breast milk, semen, cervicovaginal secretions, stool, CSF, peripheral white blood cells and plasma, amniotic fluid, bronchial lavage samples, and biopsy or autopsy specimens. All samples for isolation of viruses (except blood, which should be at room temperature) should be held at 4° C (on wet ice or in a refrigerator) until processed in the virology laboratory. Specimens for isolation of virus should be inoculated within hours of collection for an optimal isolation rate. Although isolation of CMV proves that a productive infection is present, it does not confirm an etiologic relationship with the disease process and requires careful interpretation within the patient's clinical context.

An adaptation of tissue culture is a low-speed centrifugation enhancement, monoclonal antibody culture technique, also called a shell vial assay. In this test, inoculated tissue culture cells in small vials are stained with a fluorescein-conjugated monoclonal antibody to either an early or a late CMV antigen (or both). Cells infected with CMV exhibit nuclear and membrane fluorescence 18 to 72 hours after inoculation. This rapid viral diagnostic technique is especially reliable with urine and bronchoalveolar lavage specimens and has been applied with variable results to blood and tissue specimens.[171] However,

*References 1, 3, 23, 27, 48, 191, 225, 243, 250, 264, 267, 413, 429.

maximal sensitivity and specificity are obtained when shell vials are used as an adjunct to and not in place of routine tissue culture. CMV-infected cells also can be detected by direct immunofluorescence assay on exfoliated cells in bronchoalveolar lavage specimens or in frozen tissue specimens.[193] These procedures, however, require a laboratory experienced in direct immunofluorescence assay technique.

Real-time PCR-based methods are available in many laboratories for detection and quantitation of CMV DNA. These very sensitive tests may be used to detect and to quantify CMV DNA in a variety of samples and are useful for diagnosis or prediction of CMV disease, as well as for monitoring response to antiviral treatment.*

Detection of CMV DNA in the CSF of immunecompromised patients with AIDS, of patients with primary immune disorders, and of transplant recipients seems to be a reliable diagnostic method for detection of CMV infection of the CNS, and detection of CMV DNA in the CSF of neonates with congenital CMV disease correlates with poor neurodevelopmental outcome.[26,98,177,467] Similarly, detection of CMV DNA by PCR analysis in vitreous fluid provides persuasive evidence that a patient's retinitis is CMV related.[135] CMV DNA also may be detected in the peripheral white blood cells and plasma of patients with CMV infection, and detection of CMV DNA in the plasma or serum of neonates and immunocompromised patients appears to correlate with severity of disease and viral dissemination.[295,391,408,409] Detection of CMV DNA in amniotic fluid provides prenatal diagnosis of congenital CMV infection and, when correlated with fetal ultrasonography and other clinical evaluations of the fetus, supports the presence of CMV associated in utero disease.[263] PCR assays also have detected CMV DNA in dried blood spots or Guthrie cards collected, as well as in urine and saliva, as part of neonatal screening programs and used to diagnose congenital CMV infection and disease.[40,44,58,59,447]

Another use for PCR-based diagnosis of CMV infection is the very early diagnosis of CMV infection in high-risk patients, such as transplant recipients, before the development of potentially fatal CMV disease, such as pneumonitis. This approach may allow preemptive antiviral therapy to be initiated when CMV infection appears active but before overt disease is detected.[68,468] CMV quantitative DNA detection by PCR assay is now standard for monitoring a patient's response to antiviral therapy and should be correlated with the resolution of CMV-related clinical symptoms.[131,168]

CMV pp65 antigen also may be detected in the white blood cells of patients with CMV infection and disease, and this CMV antigenemia test is still used by clinical laboratories as a rapid screen for CMV viremia, providing results the same day. It is relatively easy to perform, and the degree of antigenemia may be quantitated to monitor response to antiviral therapy.[131]

Exfoliated cells in urine or bronchoalveolar lavage specimens or cells in tissue obtained by biopsy can be examined for histologic evidence of CMV infection. Cells that are infected productively with CMV are enlarged, have type A Cowdry intranuclear inclusions, and occasionally have perinuclear inclusions. The appearance of these cells is characteristic and has been likened to owl's eyes. Immunohistochemical staining with immunoperoxidase can be used to augment the detection of these typical cells. The presence of these cells correlates with the presence of active CMV disease and may be useful clinically.

Serology

Standard serologic techniques also can be applied to the diagnosis of CMV infections. CMV IgG antibody can be determined in serum by several different methods, including complement fixation, hemagglutination inhibition, indirect fluorescent antibody assay, anticomplement immunofluorescence assay, enzyme-linked immunosorbent assay (ELISA), and latex agglutination and neutralization tests. ELISA and the indirect fluorescent antibody assay are used most commonly in clinical virology laboratories. The presence of CMV IgG antibody in a single serum specimen implies that the patient at some time has been infected with CMV. On the other hand, a negative IgG antibody determination is good evidence against current or past CMV infection because CMV antibody usually is present at the time of infection and persists for life. Severely immunocompromised patients, especially bone marrow transplant recipients, or infants and children with a primary immune deficiency, however, can lose their ability to make IgG antibody and become CMV seronegative, even though they are infected actively with CMV. This occurrence has a poor prognosis and requires immediate reconstitution with antibody and aggressive antiviral therapy until immune reconstitution is achieved. Primary infection with CMV is documented best by clear seroconversion from negative to positive CMV IgG antibody. A fourfold rise in CMV IgG antibody titer is not diagnostic of a primary infection because reactivation or reinfection also can cause titers to fluctuate. In addition, the height of the titer or ELISA index in a single serum specimen is not diagnostic of a recent infection or indicative of severity of CMV disease.

CMV IgM antibody can be determined in serum by radioimmunoassay, indirect fluorescent antibody assay, or ELISA. Both the indirect fluorescent antibody assay and ELISA are used commonly in clinical laboratories, although some indirect fluorescent antibody assays have a considerable false-positive rate. Accurate interpretation of CMV IgM antibody results requires knowledge of the methods used and careful consideration of the clinical context to exclude diseases that produce cross-reacting antibody or polyclonal responses. Test methods also should remove rheumatoid factor from the test serum, a common cause of false-positive IgM reactions. If the test is performed properly, the presence of CMV IgM antibody implies a current or recent primary CMV infection. In healthy adults, CMV IgM antibody usually persists for 6 weeks and may be present for as long as 3 to 12 months, rarely even longer, after the primary infection.[119] Commercial immunoblot and avidity assays may be used to supplement conventional CMV IgG and IgM serology.[253]

*References 69, 83, 110, 117, 170, 397, 402, 409.

The CMV IgG avidity index and IgM immunoblot assay is now available in clinical reference laboratories in many countries and continents, including Europe, Asia, and the United States. This testing may be used to help time a suspected primary infection with CMV.[143,254,346,357] A low avidity index (30%) suggests a recent primary infection, usually within 3 months, because low-to-moderate CMV avidity anti-CMV antibody may persist for 18 to 20 weeks after primary CMV infection.[254] A high avidity index (above 60%) suggests a past or recurrent CMV infection.[178] There are several manufacturers of these supplemental CMV assays, and results may vary between manufacturers, so interpretation should be within clinical context and in concert with other CMV testing, if available.[346] In immunocompromised adults experiencing clinically significant reactivation infection with CMV, CMV IgM antibody may be detected for prolonged periods.[297] The sensitivity and specificity of CMV IgM antibody determination in the diagnosis of acquired, primary CMV infection or clinically significant reactivation infection in infants and children have not been studied systematically, although clinicians frequently use this test for this purpose.

Western blot assays using viral structural proteins separated from purified viral particles or from recombinant viral proteins appear to be sensitive and specific for detection of glycoprotein-specific CMV IgG and IgM. Currently, these tests are available only in research or reference laboratories.[255]

Laboratory Diagnosis of Specific Clinical Syndromes

Pregnancy

Diagnosis of primary maternal CMV infection is best made by de novo seroconversion of virus-specific CMV IgG antibody or by the presence of both CMV IgG antibody and CMV IgM antibody associated with a low IgG avidity index.[477] For timing of the onset of CMV infection (before or in early pregnancy), CMV avidity testing is most helpful if performed during the first or early second trimester.[143] In primary maternal CMV infection, the risk for transmission of CMV to the fetus is approximately 40 percent, and it is up to 25 percent overall to the fetus for development of sequelae of some type. A maternal recurrent infection may result from reactivation of the woman's own endogenous strain(s) of CMV or by reinfection with a new strain of CMV. Recurrent CMV infection is difficult to diagnosis prenatally and may be considered if there is a significant rise of CMV IgG antibody, with the presence of IgM and a high avidity IgG index. The diagnosis of recurrent CMV infection in the mother can also be considered if she is CMV IgG antibody positive and CMV IgM antibody negative at the beginning of pregnancy yet gives birth to a congenitally infected but usually asymptomatic neonate. Routine serologic screening of pregnant women for CMV infection is controversial; and although recommended by some experts, it is not currently performed in the United States or Canada.[260] However, selective serologic screening for diagnosis should be performed for women who request it, and for those women in high-risk circumstances, including those with clinical evidence of CMV infection, such as mononucleosis during pregnancy or detection of fetal abnormalities on screening ultrasonography suggestive of in utero CMV disease.[128] Serologic screening and counseling may also be considered for child care workers and for women with a young child or toddler in the household. Prenatal diagnosis of in utero CMV infection of the fetus is best accomplished by amniocentesis, which should be done at least 7 weeks after the presumed time of maternal primary CMV infection and after 21 weeks' gestation.[205,368] This interval is important because it may take 5 to 7 weeks (at least 2 weeks) after maternal infection to produce fetal infection and subsequent replication in the kidney for a detectable quantity of CMV to be detected in the amniotic fluid.[205] Amniotic fluid may be sent for CMV culture or detection of CMV DNA by qualitative or quantitative PCR. Quantitative determination of CMV DNA in amniotic fluid that shows very high levels of DNA may predict more serious disease in the fetus and poorer outcome in the neonate. After diagnosis of maternal primary or recurrent CMV infection, monitoring of the fetus by serial ultrasound examinations should be performed every 2 to 4 weeks to detect abnormalities, which may aid in management.

Congenital Infection

Viral culture or CMV culture is the traditional diagnostic test for congenital infection with CMV.[115] The diagnosis is established by isolation of the virus from urine or saliva in the infant's first 1 to 3 weeks of life. Cell culture of urine or saliva has been used successfully to screen large numbers of neonates for congenital CMV, as well as diagnose individual patients clinically.[115,121,311,412,481] Urine cultures obtained after 3 weeks of life must be interpreted cautiously because perinatally acquired and transfusion-acquired infections with CMV may be manifested as early as 3 weeks of age.[378] Detection of nuclear inclusion-bearing renal epithelial cells in urinary sediment collected in the first 2 weeks of life also implies the presence of congenital infection. This technique is insensitive, however, compared with cell culture and is important only historically. Detection of CMV DNA in the urine, saliva, blood, or CSF of neonates by DNA PCR amplification techniques correlates with congenital infection and disease, and this method is currently used by many clinicians and laboratories for diagnosis of congenital CMV.[26,67,117,295] Detection of CMV DNA in dried blood spots (DBS) or Guthrie cards collected for neonatal metabolic screening also has been used for the retrospective and prospective diagnosis of congenital CMV infection and disease.[42,43,45,470] However, this method may not detect all congenitally infected neonates, especially those with silent or asymptomatic infection, because the level of CMV in blood is lower in asymptomatic congenital CMV infection. Studies evaluating real-time PCR assays performed on DNA extracted from DBS samples used to screen neonates for other congenital conditions have mostly shown DBS relatively insensitive for neonatal screening programs when compared with traditional

methods but possibly are useful for identification of neonates with symptomatic disease or at high risk for sequelae.[58,258,470] Genotyping may be performed by PCR assays on DNA extracted from DBS samples, providing a tool to study the possible association of CMV gB or gH genotype with disease in neonates.[121,123] Real-time PCR assays performed on saliva specimens (both liquid and dried) have shown high sensitivity compared with traditional saliva rapid culture and may be a potential screening tool for diagnosis of congenital CMV in neonates.* Neonates with high CMV DNA levels by quantitative PCR methods appear to be at highest risk for severe illness in the neonatal period and for sequelae such as progressive or late-onset hearing loss and, therefore, are candidates for CMV antiviral therapy.[251,447]

The diagnosis of fetal intrauterine CMV disease in single, twin, and multiple births also may be established by isolating the virus from amniotic fluid or detection of CMV DNA by PCR amplification in amniotic fluid obtained at least 2 weeks after the suspected time of maternal primary infection and after 21 weeks' gestation.[196,368,478] Fetal condition also can be determined by serial fetal ultrasound examinations or fetal MRI in special circumstances.[98,159,269] Fetal blood samples that show the presence of CMV DNA by PCR assay, CMV IgM antibody, thrombocytopenia, or leukopenia or elevated liver function test results also provide supportive evidence of CMV-associated fetal disease and may predict severe disease. Prenatal screening of pregnant women and prenatal diagnosis of congenital CMV infection should be accompanied by consultation with a maternal fetal medicine specialist as well as a pediatric infectious diseases specialist and a prenatal counselor knowledgeable about all the possible outcomes that can occur and all the options that are available to the parents and physician.[142,299,357]

Standard serologic tests also can be applied to diagnose congenital infection with CMV, but this approach is cumbersome, retrospective, and rarely used clinically. The absence of CMV IgG antibody in cord blood rules out congenital infection, whereas its presence may imply passive transfer from the mother or indicate a congenital infection. Serial serologic specimens also can be obtained when the infant is 1, 3, and 6 months of age. If CMV IgG antibody levels disappear during the infant's first months of life, congenital infection is ruled out. However, if CMV IgG antibody persists, the infant either was infected congenitally or acquired CMV infection perinatally or postnatally. The presence of CMV IgM antibody in cord or infant blood collected in the first 3 weeks of the infant's life suggests the diagnosis of congenital CMV infection.[184,414] However, CMV IgM antibody may be insensitive (22%) compared with urine or saliva CMV culture or CMV DNA detection for the diagnosis of congenital infection.[295]

Perinatal and Postnatal Infection

The diagnosis of perinatal infection with CMV is difficult to establish but is documented best by a negative CMV viral culture or negative CMV DNA PCR analysis of urine or saliva and negative CMV IgM antibody level at birth, followed by a positive viral culture and positive CMV IgM antibody at 8 to 16 weeks of age and persistence of CMV IgG antibody beyond 4 to 6 months of age. Postnatal primary CMV infection is diagnosed by CMV IgG seroconversion, the presence of CMV IgM antibody, and CMV excretion or "shedding" detected by culture or PCR in saliva, urine, and other body fluids.

Cytomegalovirus Syndromes in Immunocompromised Hosts

In immunocompromised patients, determination of whether serologic or virologic evidence of active CMV infection correlates with disease is difficult because CMV commonly is shed from saliva, urine, and respiratory tract secretions in these patients without clear evidence of a disease process. Therefore, detection of a productive virus infection in the organ system suspected to be involved usually is often necessary to establish the diagnosis of CMV disease in an immunocompromised patient. For example, interstitial pneumonitis caused by CMV is documented best by an open-lung biopsy specimen that shows characteristic CMV histopathologic features and positive viral culture.[107] Detection of CMV in bronchoalveolar lavage specimens also correlates with lung biopsy results.[107,170] Similarly, the diagnosis of CMV hepatitis or colitis is documented best by the presence of cytomegalic inclusion cells, isolation of CMV, or detection of CMV by DNA PCR or immunohistochemical stains from biopsy specimens. If biopsy of suspected organ is not feasible or practical, then detection of CMV viremia or rising titers of CMV DNA by quantitative PCR can support the diagnosis, because it often precedes or accompanies serious disease, such as CMV pneumonitis in bone marrow or solid-organ transplant recipients, CMV retinitis or colitis in patients with AIDS, or disseminated disease in infants with primary immune deficiency syndromes.[168,409,441]

Prospective monitoring of high-risk patients by serial samples of blood or plasma for quantitative CMV DNA PCR analysis or, alternatively, by CMV cultures of urine or blood or bronchial lavage samples and collection of serum to detect seroconversion by serologic testing is indicated and often performed because positive tests indicate the need for preemptive therapy with a CMV-specific antiviral agent, such as ganciclovir or valganciclovir, when CMV infection is active but before overt disease develops.[168,349,383,430]

TREATMENT

Antiviral agents with activity against CMV include derivatives of acyclovir, such as ganciclovir and valganciclovir, as well as foscarnet and cidofovir (Fig. 158-4).* Investigational agents, such as maribavir, are in clinical trials to determine safety, antiviral effects, and efficacy for treatment and prevention of CMV infection in transplant

*References 42, 43, 45, 59, 401, 438, 471, 472.

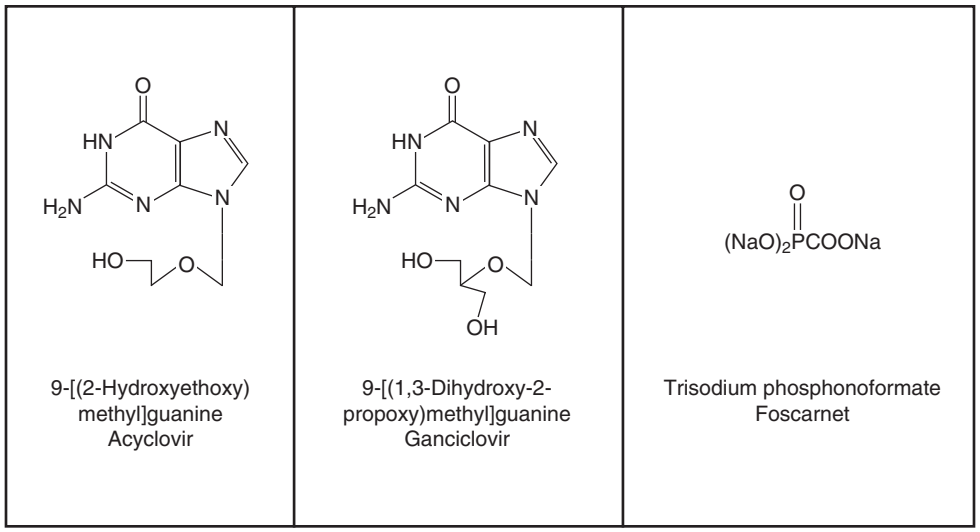

FIGURE 158-4 ■ Structures of acyclovir, ganciclovir, foscarnet.

recipients and possibly, in the near future, for congenital CMV disease.[28,273,274,464,465] Acyclovir and valacyclovir also may have limited activity against CMV under certain conditions. In addition, biological agents such as immune globulin and CMV hyperimmune globulin may benefit selected patients and novel approaches such as cell-based, cytotoxic T-cell adoptive immunotherapy also are being investigated in clinical trials.* Treatment is beneficial for adult and pediatric immunocompromised hosts as well as for neonates with congenital CMV disease.† Normal hosts with severe CMV disease also may benefit from antiviral therapy.[345]

Treatment of CMV-associated disease, such as retinitis, pneumonitis, hepatitis, colitis, esophagitis, or encephalitis, in immunocompromised hosts, such as those patients with primary immune deficiency disorders, AIDS, or transplant recipients usually involves a 2- to 3-week period of induction therapy with an intravenous antiviral medication, usually ganciclovir, as first-line treatment.‡ In special circumstances, such as suspected drug resistance or marrow suppression, foscarnet or cidofovir may be indicated.[144,423] The administration of ganciclovir plus foscarnet or cidofovir is advocated by some experts for treatment of CMV disease in infants with primary immune deficiency of T-cell or NK-cell function, to avoid emergence of resistant strains, until immune reconstitution is achieved. The induction period should be accompanied by clinical improvement and a virologic response, with reduction in the blood quantitative CMV DNA PCR titers. If the host is expected to remain severely immunocompromised after receiving successful induction therapy, or is awaiting immune reconstitution, maintenance therapy at the same dosage as treatment levels or, alternatively, a reduced dosage schedule, three to five times a week, administered intravenously or orally is indicated through the expected period of immune suppression. In patients with AIDS, primary immune disorders of T-cell or NK-cell function, solid-organ transplant recipients receiving high levels of immunosuppression, and bone marrow/stem cell transplant recipients who have not yet engrafted and shown T-cell function may receive full doses of antiviral medication as maintenance therapy. Such therapy is usually continued indefinitely, or until immune reconstitution or resolution of immune suppression.[132] In patients with AIDS or other immune deficiency conditions who have refractory CMV retinitis, treatment with a ganciclovir implant by an ophthalmologist may augment systemic therapy, but published experience evaluating this approach in infants and children is limited.[80,435] Valganciclovir, an orally bioavailable prodrug of ganciclovir, appears to be as effective as is intravenous ganciclovir for induction therapy for CMV retinitis and for mild to moderate CMV disease in solid-organ transplant recipients.[139,271] Clinical experience has shown valganciclovir is also useful for other CMV-associated illnesses in mild to moderately ill patients. If, despite administration of antiviral therapy, CMV disease persists or progresses or if a virologic response does not occur, drug resistance should be considered. Resistance to ganciclovir has been documented most commonly in patients with AIDS, but it also can occur in patients with primary immune deficiency disorders of T-cell and NK-cell function or malignant neoplasms and in solid-organ and stem cell transplant recipients.[96,213] Most ganciclovir-resistant CMV strains have a mutation in the UL97 phosphotransferase gene, but specific mutations in the UL54 DNA polymerase gene also may occur alone or in combination with UL97 mutations.[85] Most ganciclovir-resistant CMV strains are susceptible to foscarnet but may exhibit cross resistance to cidofovir, and strains simultaneously resistant to ganciclovir, cidofovir, and foscarnet also rarely may occur.[97,423] Reports of repopulation of previously susceptible wild-type strain of CMV may occur after discontinuation of ganciclovir in patients in whom a ganciclovir strain has emerged.[133] Resistant strains of CMV may

*References 21, 51, 195, 298, 339, 434.
†References 70, 107, 124, 148, 157, 189, 198, 203, 229, 235-239, 262, 301, 351, 354.

compartmentalize in the eye or brain and cause progressive disease, even if plasma and peripheral sites appear to harbor susceptible strains.

The association of CMV immune globulin administration and acute and long-term clinical outcomes in transplantation has not been well defined.[46,140,154] The administration of ganciclovir along with intravenous immune globulin or CMV hyperimmune globulin to bone marrow transplant recipients with CMV pneumonitis has been shown to increase survival over that of historical controls who were treated with a variety of other antiviral regimens, including ganciclovir alone, immune globulin alone, acyclovir, vidarabine, and interferon.[140] However, differences in the method used to diagnose CMV pneumonitis, duration of illness, and treatment regimens between study subjects and historical controls obscure interpretation of these studies.[108,263] Nonetheless, CMV-associated interstitial pneumonitis in bone marrow transplant recipients, and other types of CMV disease in immune compromised hosts, may be an immunopathologic process, and combination therapy may prevent active virus replication (ganciclovir, foscarnet, cidofovir) while enhancing immune responsiveness of cellular immunity in immune globulin–deficient patients or blunting the immune response to viral antigens already expressed on CMV-infected cells.[215,389] CMV hyperimmune globulin administered to liver transplant recipients has been shown to increase the risk for organ rejection but results in greater long-term graft and patient survival.[154] In pediatric and adult heart transplant recipients, administration of CMV hyperimmune globulin with or without antiviral prophylaxis is also associated with decreased mortality and graft loss.[398,399]

Oral maribavir has been reported in clinical trials to be possibly effective for CMV prophylaxis for prevention of CMV infection in stem cell transplant recipients and treatment of refractory or drug-resistant CMV in transplant recipients.[434,466] Clinical trials for treatment of congenital CMV infection may also be conducted. Standard immune globulin (IVIG) or CMV hyperimmune globulin, although possibly beneficial in selected patients when combined with specific antiviral therapy, should not be used alone for the treatment of established CMV infections in immunocompromised patients.[154,278,398] The combination of high-dose corticosteroids with ganciclovir does not appear to improve survival in bone marrow transplant recipients with biopsy-proven CMV pneumonitis.[352] On the other hand, a regimen combining ganciclovir with hematopoietic growth factor may allow ganciclovir to be continued in selected patients with mild marrow toxicity.

CMV hyperimmune globulin or CMV-enriched immune globulin has been shown to be of possible benefit during pregnancy in women experiencing a primary CMV infection. Case series show it appears to reduce the risk for transmission of CMV to the fetus when administered during a primary maternal infection during pregnancy, may reverse fetal abnormalities, and may improve outcome in the CMV-infected fetus with in utero disease.[74,248,298,444] Randomized clinical trials are now in progress. Treatment of infants with symptomatic congenital CMV infection with the antiviral agent floxuridine was reported first by Feigin and colleagues in 1969 and 1971.[147] More recent reports suggest that antiviral agents, such as ganciclovir and valganciclovir, benefit congenitally infected infants.* Anecdotal reports, case series, and randomized clinical trials have shown clinical and virologic improvement in congenitally infected neonates treated with ganciclovir and valganciclovir.† A multicenter phase I/II study of the pharmacokinetics, antiviral effects, and safety of intravenous ganciclovir was conducted in 47 neonates with symptomatic congenital CMV disease and neurologic involvement.[433,458,484] In this study, a 6-mg/kg dose of ganciclovir administered by a 1-hour infusion every 12 hours for a period of 6 weeks produced a significant reduction in the quantity of urinary virus excretion; however, viral shedding recurred when ganciclovir treatment was discontinued. Neutropenia, thrombocytopenia, and elevated levels of liver enzymes also were observed. Limited clinical follow-up in 30 of the original 47 infants showed that hearing loss improved or stabilized in 16 percent of the treated infants. Subsequently, a phase III, multicenter, randomized clinical trial enrolled 100 infants and was completed in 1999.[237] In this study, ganciclovir treatment in the neonatal period appeared to have an impact on hearing loss by slightly improving hearing, maintaining normal hearing, or preventing hearing deterioration, as measured when the infants reached 6 and 12 months of age. Because only 44 percent of the enrolled infants were assessed in follow-up at 1 year of age, a long-term follow-up study of treated infants is needed to determine whether the early beneficial effects last through childhood and adolescence. In addition to an effect on hearing loss, treatment provided more rapid resolution of hepatitis, when present, and improved short-term growth in weight and head circumference and developmental milestones.[310,311] Currently, most experts agree antiviral treatment is indicated in neonates with congenital CMV disease with neurologic involvement and/or eye disease and/or sensorineural hearing loss. Some experts recommend treatment of all symptomatic neonates to reduce the risk for late-onset hearing loss and improve neurodevelopmental outcome. For maximum benefit, treatment should begin within the first month of life.

The decision to administer antiviral therapy to a neonate with congenital CMV disease remains at the discretion of the clinician and should be based on disease severity and risk factors for sequelae.[395,428,456] Short-term antiviral therapy is likely to benefit infants who have multisystem disease with viremia detected by positive CMV quantitative DNA PCR assay, pneumonia, severe or persistent thrombocytopenia, hepatitis, enterocolitis, or active sight-threatening retinitis.[211] In these clinical circumstances, a reduction in viral load should improve the infant's clinical condition and resolve end-organ disease. However, the sustained effect beyond 1 year of life of short-term treatment on long-term sequelae, such as hearing loss and neurodevelopmental disabilities, is not clear at this time and requires long-term follow-up studies to confirm this benefit.[71] A longer duration of therapy for 6 months or longer, with an oral antiviral agent such as valganciclovir, may improve outcomes and

*References 71, 249, 283, 284, 294, 310, 311, 380, 476.
†References 202, 300, 311, 355, 428, 436.

reduce the development of long-term sequelae, including hearing loss, in these infants.[19,428,456] Anecdotal reports and phase I pharmacokinetic and pharmacodynamic studies have demonstrated that valganciclovir oral solution provides plasma concentrations and antiviral effects similar to those levels achievable with use of intravenously administered ganciclovir in neonates.[236,289] Clinical trials evaluating the long-term benefits of prolonged treatment with oral valganciclovir in congenitally infected infants are needed. Case series of children with asymptomatic congenital CMV infection and hearing loss treated with ganciclovir and valganciclovir have reported improvement in hearing loss with treatment.[198,476] In addition to specific antiviral therapy, management of congenitally infected infants includes supportive care, nutritional and feeding support, and control of seizures. If thrombocytopenia is severe and persistent, platelet transfusions and immune globulin also is of benefit. Long-term management includes careful attention to nutrition to ensure adequate growth, serial hearing tests to detect progressive or late-onset hearing loss, developmental assessments to evaluate for cognitive and motor disabilities, physical therapy, occupational therapy, and ophthalmologic evaluations to follow up abnormalities present in the neonatal period, such as retinitis, and to monitor for vision-threatening, late-onset sequelae.[456,460]

PREVENTION

Prevention of CMV disease is important because it causes significant morbidity and mortality in a variety of patients. In immunocompromised hosts, it also is associated with the development of other complications, such as opportunistic coinfections and graft rejection in transplant recipients, and it increases resource use in transplant programs. In neonates and infants with primary immune deficiency disorders of T-cell and NK-cell function, congenital or acquired CMV infection is sight and life threatening. In premature neonates, potentially fatal viral sepsis syndromes can occur. Furthermore, congenital infection is a leading cause of deafness, vision loss, and developmental disabilities in children. Approaches to the prevention of CMV disease include the use of CMV-seronegative blood products, selection of CMV-seronegative donors for transplant recipients, passive immunoprophylaxis with immune globulin, prophylactic or preemptive use of antiviral agents, active immunization with a CMV vaccine, and behavioral strategies to reduce exposures to CMV-infected secretions.

Blood Product, Human Milk, and Transplant Donor Selection

Transplant recipients who are CMV seronegative and receive solid-organ or bone marrow or stem cell transplants from CMV-seropositive donors are at significant risk for acquiring symptomatic primary CMV infection. Therefore, whenever possible, CMV-seronegative recipients should receive transplants from CMV-seronegative donors and all blood product transfusions should be from CMV-seronegative donors. CMV-seropositive transplant recipients may also experience CMV infection and disease after transplant.

Infection with CMV in seriously ill CMV-seronegative neonates can be prevented by use of blood products from CMV-seronegative donors or by use of frozen deglycerolized red blood cells.[63,475] Saline-washed red blood cells also reduce but do not always prevent the acquisition of CMV infection in neonates, even though as many as 90 percent of the leukocytes can be removed by this method.[116]An alternative method of preparing leukocyte-depleted blood, filtration through a cotton-wool filter, appears to prevent posttransfusion acquisition of CMV infection in neonates.[169] Many institutions now provide CMV-seronegative or leukocyte-depleted blood products routinely to all neonates or to all low-birth-weight neonates, as well as other immune compromised infants and children, regardless of the CMV serostatus of the mother.

Ingestion of CMV-positive breast milk by premature infants, especially those of less than 28 weeks' gestation, has been associated with illness. Therefore, donor selection for CMV seronegative donors or pretreatment through pasteurization or freeze-thaw cycles of human milk administered to extremely premature infants may reduce the risk for acquisition of CMV-associated disease in these infants.* Healthy term infants may receive breast milk from CMV-seropositive mothers and donors.[327]

Passive Immunoprophylaxis

Although immune globulin, CMV hyperimmune globulin, or CMV-enriched immune globulin should not be used alone for the treatment of established CMV disease in immunocompromised patients, these preparations may be used with antiviral agents to treat CMV disease in selected patients and to prevent the acquisition of serious CMV disease in selected immunocompromised patients. The association of CMV immune globulin administration and acute and long-term clinical outcomes in transplantation has not been well defined, but some studies suggest potential benefit.[46,154]

Passive immunization remains controversial, however, partly because studies or protocols have used different dosages (100 to 400 mg/kg) administered at varying intervals (1 week before transplantation and every 1 to 3 weeks after transplantation) for varying times (60 to 120 days). CMV immune globulin has been shown to decrease the incidence of symptomatic CMV disease from 60 to 21 percent in CMV-seronegative renal transplant recipients who received a kidney from a CMV-seropositive donor.[400] CMV immunoprophylaxis also has decreased the incidence of CMV pneumonitis in CMV-seronegative bone marrow transplant recipients who did not receive granulocyte transfusions.[60,281,350,464] CMV hyperimmune globulin administered to liver transplant recipients has been shown to increase the risk for organ rejection but improves long-term graft and patient survival.[154] In pediatric and adult heart transplant recipients, administration of CMV hyperimmune globulin with or without antiviral prophylaxis is also associated with decreased mortality and graft loss.[398,399] A clinical trial with a CMV-specific monoclonal antibody

*References 81, 220, 274, 312, 445, 446.

specific to CMV gH (MSL-109) did not show benefit in a randomized, placebo-controlled, double-blind study in allogeneic stem cell transplant recipients, nor in infants with congenital CMV infection.[53]

The use of immunoglobulin preparations (CMV hyperimmune globulin, CMV-enriched immune globulin, and standard human intravenous immunoglobulin that may contain high titers of CMV IgG) in pregnant women with primary CMV infections to prevent or to ameliorate CMV infection in the fetus has been reported, and results were favorable.* CMV immunoglobulin reduces placental inflammation and thickening, neutralizes virus with high avidity antibodies, and reduces cytokine-mediated cellular immune responses.[13,14,248] In one case-control study, the severity of neurodevelopmental and hearing disabilities in the infants and children of mothers with primary CMV infection who received CMV immunoglobulin was less when compared with those who did not receive CMV immunoglobulin.[298] However, despite these promising results, definitive recommendations for the routine clinical use of CMV immunoglobulin immunoprophylaxis in women experiencing primary CMV infection during pregnancy, or to treat or ameliorate in utero CMV disease in the fetus, await results of randomized clinical trials.[288,299,301,339]

Prophylaxis and Early Preemptive Therapy with Antiviral Agents

The prophylactic use of antiviral agents in transplant recipients reduces the incidence of serious CMV disease.[139] However, no regimen has been shown to completely prevent the acquisition of CMV infection or disease in all types of transplant patients.[327]

Acyclovir is used by some clinicians as prophylaxis for CMV disease in organ transplant recipients, despite evidence that acyclovir is inactive against most strains of CMV and CMV disease occurs despite such prophylaxis.[394] In one study, intravenous administration of acyclovir 500 mg/m^2 of body surface area per dose every 8 hours for 5 days before and 30 days after transplantation to CMV-seropositive bone marrow transplant recipients appeared to reduce the incidence of CMV disease.[282] High-dose oral acyclovir administered 1 day before and for 12 weeks after transplantation also has been shown to reduce the incidence of CMV disease and infection in renal transplant recipients.[38]

The prophylactic administration of human leukocyte interferon-α has been shown to reduce the incidence of severe CMV disease in renal transplant recipients, but it has no apparent benefit in bone marrow transplant recipients, and it is not used routinely in any patient population.[91,199,204,353]

The prophylactic use of intravenous ganciclovir and oral valganciclovir in solid-organ and bone marrow and stem cell transplant recipients at high risk for acquiring serious CMV disease is now routine and favored over preemptive treatment.[139,232,272] Prophylaxis treatment regimens vary, however, and it is difficult to make recommendations about which regimen is best. Most solid-organ transplant recipients appear to benefit from intravenous ganciclovir 5 to 10 mg/kg/day administered once or twice daily for 2 to 6 weeks after transplantation, usually followed by continuing antiviral prophylaxis with a reduced dose of ganciclovir or with orally administered valganciclovir.[30,437] Administration of a short 2-week course of ganciclovir near the time of transplantation, without continuing antiviral prophylaxis, does not appear to reduce significantly the incidence of CMV disease in most solid-organ transplant recipients studied.[30,437] Antiviral prophylaxis not only reduces the risk for serious CMV disease but also improves solid-organ graft survival and overall patient survival.[139] A duration of prophylaxis with oral valganciclovir extended to 200 days compared with 100 days after transplantation appears to significantly reduce the incidence of CMV disease. However delayed-onset CMV disease may still occur and antiviral resistance may emerge in some patients.[232,272]

Intravenous immune globulin or CMV hyperimmune or CMV-enriched immune globulin when it is given with a prophylactic antiviral agent in solid-organ recipients improves allograft and patient survival. In bone marrow transplant recipients, the administration of ganciclovir prophylaxis after marrow engraftment reduces CMV disease. In addition, some ganciclovir-treated bone marrow transplant recipients may experience prolonged neutropenia.[176] Even though most transplant centers have adopted prophylaxis strategies with antiviral agents and CMV hyperimmune globulin to reduce the risk for CMV infection and disease, some experts believe the strategy of preemptive antiviral therapy has certain advantages over strategies that either treat only patients with overt clinical disease or administer prophylactic antiviral agents to many patients at risk, only a few of whom appear to benefit.[167] In addition, preemptive or very early antiviral treatment strategies include viral surveillance of blood, urine, and respiratory samples. Viral surveillance of these samples can be by standard viral culture, viral antigen detection, viral nucleic acid detection by qualitative or quantitative PCR assay, or a combination of these tests. Detection of CMV viremia, or rising quantitative CMV DNA PCR levels, and culture-positive or PCR-positive bronchoalveolar lavage samples have correlated with the development of serious CMV disease in transplant recipients.[68] In bone marrow, stem cell, and solid-organ transplant recipients, early intervention with intravenous ganciclovir therapy at the time of positive CMV surveillance cultures is beneficial.[176,383,396] Another approach to preemptive therapy, that is currently not practiced routinely and that does not entail viral surveillance techniques, is to administer an antiviral agent, such as ganciclovir, only during times of rejection, when CMV reactivation is likely to occur. This approach has been modestly successful in high-risk renal transplant recipients.[197] Simultaneous virologic and immunologic follow-up is the best approach for monitoring CMV infection in transplant recipients. Lack of immune reconstitution or presence of graft rejection or graft-versus-host disease usually heralds repeated episodes of recurrent or persistent CMV infection or disease, requiring multiple or prolonged courses of antiviral and immunoglobulin therapy.[167] Antiviral resistance to single or multiple agents

*References 13, 14, 74, 106, 299, 301, 444.

may occur in these high-risk patients and has been increasingly recognized as a significant problem.[85]

Active Immunization

Prevention of acquisition of CMV disease through active immunization is a priority for the 21st century.[379,419] Universal vaccination of adolescent females to protect their future children against congenital CMV infection has been determined to be cost effective, if a CMV vaccine with at least 61 percent efficacy is available.[122] In addition to pregnant women and their fetuses, transplant recipients would benefit greatly if a safe, effective CMV vaccine became widely available.[24,223,379,381] The ideal CMV vaccine should be safe, effective, immunogenic, and cost effective. It should prevent the development of primary CMV infection without causing chronic persistent infection. The vaccine also should not be capable of infecting the fetus, and it should not be oncogenic. However, because the optimal composition and strategy for an ideal CMV vaccine that would be licensed for clinical use remains to be discovered, research continues in animal models and human clinical trials.[50,172,185,379,382]

In 1975, Plotkin and associates[336] characterized and reported a candidate CMV vaccine strain, Towne 125, that was isolated originally from the urine of a congenitally infected infant named Towne. Since then, more than 500 subjects, including renal transplant recipients and healthy adult male and female volunteers, received the investigational Towne 125 vaccine.* Studies of these subjects showed that Towne 125 is attenuated and relatively safe and that it induces humoral and cellular immunity in both healthy and immunosuppressed subjects.

The Towne 125 vaccine also appeared to be protective in a randomized, placebo-controlled study of 91 immunosuppressed renal transplant recipients.[335] In this study, 30 CMV-seronegative vaccine recipients received a kidney from a CMV-seropositive donor, and the incidence of severe CMV disease was significantly lower in the vaccine group than in the placebo group. However, the CMV infection rate did not differ significantly between the groups, and members of both groups experienced mild to moderate CMV disease. Subsequent studies have confirmed that CMV-seronegative renal transplant recipients who receive a live attenuated CMV vaccine are more resistant to serious CMV disease.[337] Another vaccine strategy investigated was the development of mutant hybrid strains of CMV that combine the safety of the Towne strain with the more virulent and potentially more immunogenic Toledo strain. Early clinical trials demonstrated, enhanced immunogenicity and possibly, however, also enhanced virulence.[12,333,424] Other investigators have evaluated subunit vaccines for CMV that contain purified glycoprotein B (gB) complexed with a powerful adjuvant—alpha replicon particle vaccines and live-attenuated CMV vaccines.[65,146,319,424] A CMV gB vaccine with MF59 adjuvant recent showed vaccine efficacy of 50 percent and provided proof that vaccination has the potential to decrease maternal and congenital CMV infection.[317,325] Most recently, the cellular immune system has been targeted by "DNA vaccines" that encode gB and appear to induce protective cellular immunity against CMV. Finally, adoptive immunotherapy with sensitized T cells has shown promising results for prevention of CMV infection and disease in transplant recipients and is being evaluated in clinical trials.[195]

*References 82, 156, 223, 334-336, 338, 417.

Behavioral Strategies to Prevent Primary Cytomegalovirus Infection

With the current complexities associated with the development of a CMV vaccine and the challenges of administering effective antiviral therapy, an alternative practical option for prevention of CMV infection during pregnancy and other high-risk times of life is education to increase public awareness about CMV and its modes of transmission.* Surveys have documented that knowledge about cytomegalovirus around the world is low.[265] Most studies have shown less than 20 percent of responders to CMV knowledge surveys have heard of CMV. For example, approximately 7 percent of men and 13 percent of women in one study from the 2010 HealthStyles survey had even heard of CMV, even though it is considered a common viral infection.[79,369] Educational materials are available from clinicians, from public health and university web sites,† as well as nonprofit organizations and social media web sites. These sites provide factual information to promote CMV awareness and guidelines for reducing the risk for CMV transmission to pregnant women, women of child-bearing age, and other susceptible individuals.[368] Reliable, relatively inexpensive serologic evaluation is available, so all women contemplating pregnancy should know their CMV serologic status. In addition, because epidemiologic studies have shown a major source of CMV infection to be close contact with young children, women who are pregnant, especially women who are known to be CMV seronegative, should be aware that a high percentage of young children are infected actively with CMV and that while pregnant they should exercise good hygienic practices when in close contact with young children, especially those who attend daycare centers or are known to have an active CMV infection.[76,79,105,320] Studies from the United States and Europe have shown that the incidence of child-to-parent transmission of CMV may be reduced by interventions that identify susceptible pregnant women and educate them about increasing protective behaviors, such as handwashing after diaper changes and wiping tears and nasopharyngeal mucus and decreasing risky behavior for acquiring CMV, such as kissing on the mouth and sharing eating utensils.[10,11,105,153] Many experts recommend women of childbearing age should be aware about CMV and practice recommended hygienic precautions during pregnancy.[76,105,121,181] In addition, CMV can be transmitted from husband to wife, and if the spouse or partner experiences a CMV mononucleosis syndrome, a CMV-seronegative woman may wish to consider avoiding pregnancy for an individualized period of time.[118]

CHAPTER 159

Epstein-Barr Virus

Charles T. Leach • Ciro V. Sumaya • Gail J. Harrison

Epstein-Barr virus (EBV) is an extremely common herpesvirus that is the etiologic agent of classic infectious mononucleosis (IM).[492] Evidence that the virus also plays a principal role in the development of certain lymphoproliferative diseases and epithelial malignant neoplasms continues to mount. Its ability to remain in a dormant (latent) state after infection allows reactivation and recurrence of disease, especially under immunosuppressive conditions. Unfortunately, antiviral agents have little effect on EBV-associated diseases, but progress is being made toward improved treatment of EBV-associated malignant diseases. Eventually, vaccination may provide protection for those persons at highest risk for development of severe disease manifestations.

This chapter reviews progress in understanding of the immunobiology of EBV and its disease associations. Enhanced understanding of EBV is leading to newer diagnostic methods and improved management of EBV-associated diseases.

HISTORY

One can identify four distinct periods of history related to IM and its etiologic agent, EBV[127,457]: (1) early descriptions of IM, (2) identification of the heterophil antibody test associated with IM, (3) discovery of EBV in Burkitt lymphoma (BL) cells, and (4) association of acute EBV infection with heterophil-positive IM.

Credit for the original description of a disease consistent with what is now called infectious mononucleosis commonly is given to a German physician named Pfeiffer,[403] who in 1889 described relatively mild illness characterized by fever and lymphadenopathy; later, his report was translated into English.[336] The illness came to be known as Drüsenfieber, or glandular fever. Although some cases of glandular fever were typical of what is now recognized as IM, certain characteristics of this illness, including its predominance in children and familial clustering, did not fit. In England, glandular fever and IM have become synonymous, yet many experts consider glandular fever to be a different illness.

In the early 1900s, numerous case descriptions of illnesses epidemiologically and clinically compatible with IM appeared.[56,190,241] However, because the illness now recognized as IM had not yet been described and these illnesses were suggestive of leukemia, most of them were reported erroneously as acute leukemia with spontaneous cure. Although the term *infectious mononucleosis* was used first in one of these case reports,[241] the illness was not distinguished from leukemia until Sprunt and Evans published their landmark paper in 1920.[482] These authors described a series of patients with clinical syndromes consistent with typical IM, including classic hematologic findings. A subsequent report by Downey and McKinlay provided a more detailed description of the hematologic manifestations.[110]

Although most cases of IM could be identified by hematologic and clinical findings, not until a specific serologic test was identified in 1932 could classic IM be better defined. In the course of investigating heterophil antibodies in serum from patients with rheumatic fever and other diseases, Paul and Bunnell[395] noted high titers of heterophil antibodies in serum from a control patient. Further investigation revealed that the control patient was a medical student with IM. Evaluation of sera from three other patients confirmed the presence of high titers of heterophil antibodies during acute IM.

In 1958, Dennis Burkitt, an English surgeon, described 38 cases of "round-cell sarcoma" developing in children and adolescents living in one region of Uganda, Africa.[54] Eventually, the tumors were determined to represent lymphomas, not sarcomas. Although a new mosquito-borne infectious disease was suspected as the culprit initially, Epstein and Achong[118] eventually were able to cultivate and evaluate tumor cells by electron microscopy; they noted particles with ultrastructural characteristics similar to those of herpes simplex virus (HSV), which had been described a few years earlier. Further work established this virus as the fourth human herpesvirus (after HSV-1, HSV-2, and cytomegalovirus [CMV]).

The association between this new herpesvirus and IM was noted serendipitously in 1968 when an IM-like illness developed in a technician working in the laboratory of the Henles.[205] Stored, pre-illness serum from this technician contained neither heterophil nor EBV antibodies, but both heterophil and EBV antibodies appeared 6 days after the onset of symptoms. In addition, virus was cultivated from the technician's peripheral blood cells. Subsequent testing of serial specimens from other patients with IM also demonstrated seroconversion to EBV in all cases. This work as well as studies from Yale University,[126,374] among others, firmly established EBV as the cause of IM. Investigators subsequently showed that EBV has the capacity to transform (immortalize) human B lymphocytes in vitro, which allows the derivation of EBV-transformed B-lymphoblastoid cell lines capable of being propagated indefinitely in tissue culture.[207,407]

VIROLOGY

EBV is in the family Herpesviridae, subfamily Gammaherpesvirinae, genus *Lymphocryptovirus*.[98] Its closest relative, human herpesvirus 8 (also known as Kaposi sarcoma–associated herpesvirus), is also a gammaherpesvirus. Although its taxonomic name (human herpesvirus type 4) is used by most bibliographic search services, most scientists and physicians use its historic name.

Structure and Genome

The structure of the EBV is typical for a member of the herpesvirus family; it displays an inner core of DNA surrounded by a nucleocapsid, tegument, and envelope.[119] Within the inner core, which measures approximately 45 nm, exist approximately 184 kilobase pairs (kbp) of double-stranded DNA coding for nearly 100 proteins. The surrounding nucleocapsid displays icosahedral symmetry (162 capsomeres) and measures approximately 100 to 110 nm in diameter. Outside the capsid lies the tegument, which consists of loosely packed, amorphous proteinaceous material, and the tegument in turn is surrounded by the viral envelope containing glycoprotein spikes. The complete virion measures approximately 150 to 220 nm.

The entire EBV genome has been sequenced.[28] The structure of EBV is characteristic of all the herpesviruses, with short and long sections of "unique" sequences (U_S and U_L, respectively) separated by a major internal repeat region (IR_1) generally consisting of 6 to 12 direct repeats of a 3-kbp sequence.[102] The virus also has numerous other regions of repeated nucleotide sequences, including direct repeat of a 0.5-kbp sequence at its termini.

MOLECULAR BIOLOGY

Much of the early information about the molecular biology of EBV comes from laboratory strains derived from BL tumor cell lines (e.g., HR-1)[216] and marmoset lymphoid cell lines transformed by viral strains infecting human beings (e.g., B95-8).[355]

Replication

EBV infection of cells is initiated by attachment of EBV glycoprotein gp350 to a cell surface receptor (CR2, CD21) found primarily on B lymphocytes and nasopharyngeal epithelial cells[472,563] and less commonly on other cells.[262,345,558] This receptor is the same as the surface moiety that functions as the receptor for the third component of serum complement (the C3d receptor).[136] Penetration of the cell requires a complex consisting of viral glycoproteins gH, gL, and gp42 (for B-cell infection), whereas only gH and gL are necessary for infection of epithelial cells[534]; gp42 binds with human leukocyte antigen (HLA) class protein found in B cells but not present in epithelial cells. After entering the B lymphocyte, the virus is transported through the cytoplasm and is stripped of its envelope in endocytic vesicles.[371] Subsequently, the viral genome circularizes and is maintained in the cell nucleus as a multicopy plasmid (or episome).[327] The initial and predominantly replicative (lytic) EBV infection probably occurs in epithelial cells of the oropharynx and adjacent structures,[470,551] with virus then transmitted to circulating B cells passing through these lymphoepithelial tissues. Although lytic genes may be found in EBV-associated tumors (e.g., posttransplant lymphoproliferative disease [PTLD]),[358] the overall proportion of replicating cells is far surpassed by latently infected B cells. In contrast, after infection of epithelial cells occurs, active replication occurs and leads to lysis and death of the cell. Alternating replication of viral glycoproteins in B cells and epithelial cells appears to modify the viral tropism, allowing virus from replicating B cells to infect epithelial cells more efficiently, and vice versa.[46] Recent data also suggest that monocytes may play an important role as a reservoir for EBV and could provide an important link for the transfer of virus from B cells to the oral epithelium.[521] Proteins synthesized during viral replication are important for viral gene regulation, replication of the genome, production of mature particles, and modulation of the immune system.

Latency

Latently infected B cells are the primary reservoir of EBV in the body. In a typical healthy EBV-seropositive adult, 1 to 50 per million B cells are infected with EBV, and this condition remains relatively constant during many years.[25] Although more than 80 gene products may be expressed during active viral replication, only a limited number are expressed during viral latency. This is one method by which the virus limits cytotoxic T-cell recognition of EBV-infected cells. The EBV gene products that may be expressed during latency include six nuclear proteins (EBV nuclear antigens [EBNAs] 1, 2, 3A, 3B, and 3C and a leader protein [EBNA-LP]); three membrane proteins (latent membrane proteins [LMPs] 1, 2A, and 2B); two small, nonpolyadenylated (noncoding) RNA molecules (EBV-encoded RNAs [EBERs] 1 and 2); and the Bam H1A rightward transcripts (BARTs).

On the basis of in vitro genetic and somatic cell hybrid experiments, three different patterns of latent gene expression can exist in EBV-infected cells from patients with EBV-associated disease.* Type I latency, exemplified by cells derived from BL, exhibits a limited repertoire of genes consisting of EBNA-1, EBERs, and BARTs. Type II latency typically is observed in cells derived from Hodgkin disease (HD) and nasopharyngeal carcinoma (NPC). Besides EBNA-1, EBERs, and BARTs, these cells also express latent membrane proteins (LMP-1, LMP-2A, LMP-2B). Lymphoblastoid cell lines as well as tissues from patients with IM, PTLD, and acquired immunodeficiency syndrome (AIDS)–associated lymphomas display the broadest pattern of latent gene expression (type III), wherein all genes associated with latency are expressed.[291,453,511,562] A "type 0" latency also may exist within circulating EBV-infected memory B cells from

*References 102, 291, 428, 499, 513, 559, 565.

healthy persons, wherein only EBERs and BARTs are expressed.[428] Although these latency expression pattern categories may be useful for histopathologic characterization, significant heterogeneity among histopathologically similar tumors can occur.

A brief description of latency-associated EBV genes follows.

EBNA. EBNA-1 is required for replication and maintenance of EBV episomal DNA in latently infected cells.[291] It also interacts with various viral promoters in regulating transcription of the EBNAs (including itself) as well as LMP-1. As mentioned previously, amino acid repeat structures in the EBNA-1 protein protect it from proteosomal degradation, thereby stabilizing protein levels and possibly preventing presentation by major histocompatibility complex class I molecules.[316] A role for EBNA-1 in B-cell transformation and oncogenesis remains somewhat debatable.[499] EBNA-2 clearly is a viral oncogene that is essential for cellular transformation. It transcriptionally activates several viral genes (e.g., LMP-1, LMP-2A) and cellular genes (e.g., CD21 and CD23) by its interaction with the DNA-binding protein RBP-Jκ (Jκ recombination-binding protein).[203] All three EBNA-3 proteins (A, B, and C) are transcriptional regulators of key cellular and viral promoters, but only 3A and 3C have proved to be indispensable for in vitro B-cell transformation.[518] The primary regulatory functions of EBNA-3 proteins, like those of EBNA-2, occur through interactions with RBP-Jκ.[432] Moreover, EBNA-3C is able to overcome the arrest of the retinoblastoma (Rb) gene cell cycle and increases expression of LMP-1.[325] The exact mechanistic contribution of EBNA-LP (also called EBNA-5) to B-cell immortalization is not well understood. Although EBNA-LP is not required for transformation of B cells, the absence of EBNA-LP drastically reduces the efficiency of transformation.[340] EBNA-LP possibly contributes to immortalization by enhancing EBNA-2–mediated transcriptional activation of the LMP-1 gene.[399] Also, previous studies have demonstrated that EBNA-LP cooperates with EBNA-2 in driving cells into the G_1 cell cycle phase by binding and inactivating the tumor suppressors Rb and p53.[501]

Latent Membrane Proteins. Like EBNA-2, LMP-1 (a viral oncogene) is essential for EBV transformation of B cells and appears to be the main transforming protein of EBV. LMP-1 displays pleiotropic effects when it is expressed in EBV-infected cells. Most prominently, LMP-1 mimics the CD40 B-cell receptor, which plays a key role in the activation and differentiation of B cells.[280] The protein also induces expression of antiapoptosis genes (e.g., BCL-2 and A20) as well as activation and adhesion of B cells.[457] LMP-2 consists of two transmembrane proteins: LMP-2A contains two intracytoplasmic domains (at the amino and carboxy termini) and 12 integral membrane domains; LMP-2B differs by the lack of the amino-terminal cytoplasmic domain. LMP-2 generally is recognized as a modifier of normal B-cell development, promoting maintenance of viral latency.[565] LMP-2A mimics the B-cell receptor and alters normal B-cell signal transduction by inducing a range of genes involved in cell cycle induction, inhibition of apoptosis, and suppression of cell-mediated immunity. Functions of LMP-2B are less well described, but a report indicates a key role in regulating LMP-2A activity.[443]

EBERs. These two small nonpolyadenylated (noncoding) RNAs are the most abundant viral transcripts found in latently infected EBV cells (approximately 10^7 copies per cell) and, indeed, serve as important diagnostic tools through the use of in situ hybridization (see later section on diagnosis, EBV nucleic acid). Studies indicate that EBERs may play important roles in viral persistence and oncogenesis for some tumors. For example, EBERs bind to double-stranded, RNA-activated protein kinase R, which serves to inhibit interferon-inducible apoptosis.[369] Moreover, EBERs play a key role in the maintenance of malignant phenotypes of BL cells.[503]

BARTs. These consist of a family of differentially spliced RNAs, first identified in NPC and later found in other EBV-associated malignant diseases.[475] Although noted abundantly in all forms of latency, protein products of their open reading frames have not been clearly identified.

Transformation

In vitro, resting human B cells infected with EBV develop into lymphoblastoid cell lines. These cells are described as immortalized or transformed because instead of following one of two normal pathways (differentiation or apoptosis [programmed cell death]), they proliferate continuously.[269] Current evidence suggests that EBV proteins coded by six latency-associated genes (described previously) are important for this cell transformation process: EBNA-2 and LMP-1 are absolutely essential; EBNA-1, EBNA-3A, EBNA-3C, and EBNA-LP also play critical roles.[428] The remaining latency-associated viral gene products, although not essential for transformation, are involved in the initiation and maintenance of cell transformation.

EBV generally transforms relatively mature B lymphocytes, secreting a complete immunoglobulin product (heavy chain plus light chain).[50,379] EBV also is capable of infecting and transforming B cells in earlier stages of development (e.g., pre-B cells [producing only μ chains] and lymphoid precursors lacking immunoglobulin gene rearrangement)[146,147,269,276]; mature plasma cells cannot be infected by EBV. Tumor cells and cell lines from BLs are B cells that generally express small amounts of immunoglobulin, which may be detected as surface immunoglobulin molecules, cytoplasmic/secreted molecules, or both. The major heavy-chain isotype expressed by Burkitt tumors appears to be μ chain (IgM), although other isotypes can be observed.[379] Similarly, the EBV-infected cells observed in the blood of persons with mononucleosis and the tumor cells found in immunodeficient hosts with EBV-associated lymphoproliferative diseases and lymphoma are B lymphocytes; these EBV-infected cell populations may include cells producing any of the major classes of human immunoglobulin (IgG, IgA, or IgM).[50,379,434,435] EBV-related malignant lymphoproliferations in immunosuppressed patients may be polyclonal, oligoclonal, or monoclonal; the lymphoproliferations probably are polyclonal at first but eventually progress to monoclonality.[101] BLs, on the other hand, always appear to be monoclonal at initial evaluation.[34,379]

EBV Genotypes

Two genotypes of EBV (EBV-1 and EBV-2) were identified in the 1980s on the basis of marked genomic differences in EBNA LP, 2, 3A, 3B, and 3C genes.[444,451] By use of this methodology, seroepidemiologic and virologic studies suggested geographic differences in the prevalence of these two genotypes, with both types found widely in central Africa and elsewhere but type 1 predominating in Western countries. Most EBV-infected persons appear to harbor one genotype, yet immunocompromised persons may be coinfected with both type 1 and type 2 genotypes. More detailed genetic analyses have been conducted, revealing more subtle differences in the genome and the presence of multiple EBV "strains" in healthy patients.[468,516,532] Multiple strains probably are acquired at the time that the initial EBV infection occurs,[516] yet it is possible that superinfections with other EBV strains occur after primary infection with one strain. No substantial evidence supports the view that any one genotype (or strain) is responsible for specific lymphoproliferative diseases.[414]

IMMUNOPATHOGENESIS

Infectious Mononucleosis

EBV elicits a wide range of immunologic responses in humans, partly because of its propensity to infect B lymphocytes. In a normal host, the immunologic effects probably are responsible for most EBV-associated disease manifestations. Both cellular and humoral immunity develop in response to EBV infection. Detection of humoral antibodies directed against viral capsid and nuclear proteins is important for establishment of the diagnosis of acute infection. However, the responsibility for effective control of EBV infection lies primarily with the cellular immune elements.[168] Two to 7 weeks after exposure, up to 20 percent of circulating B lymphocytes become infected during primary EBV infection, although 1 percent is typical.[433] A brisk cellular immune response ensues. In the acute stage, proliferating EBV-infected B cells are controlled principally by natural killer (NK) T cells, helper ($CD4^+$) T cells, and cytotoxic-suppressor ($CD8^+$) T cells.[427] In some rare EBV syndromes, these T cells can themselves become infected and directly cause disease.[250,283] In adults the proliferation of $CD8^+$ T cells causes a temporary inversion of the normal $CD4^+/CD8^+$ T-cell ratio; however, $CD8^+$ T-lymphocyte expansion is less marked in children.[537] After this T-cell response, the number of EBV-infected B cells falls dramatically during the next 4 to 6 weeks to concentrations of approximately 1 per million circulating B cells.[436] During convalescence, HLA-restricted cytotoxic T lymphocytes keep EBV in check, primarily by targeting the latently expressed EBNA-3 protein.[505]

During the acute stages of IM, despite a brisk immune system response to EBV, widespread and extensive impairment in general cell-mediated and humoral immunity also exists. For example, low or absent delayed-type hypersensitivity reactions develop in response to tuberculin and other antigens.[187,339] In addition, T cells from patients with IM display unusually weak proliferative responses when they are exposed to recall antigens (e.g., *Candida albicans*, tetanus toxoid).[359,510] Although EBV-specific cytotoxic and suppressor T cells appear during acute infection, the T-cell response is primarily nonspecific and HLA unrestricted.[284,285,392,423] Furthermore, a polyclonal humoral response occurs during acute infection with EBV.[442] Each B cell committed to one isotype continues to produce that isotype after transformation of EBV, thereby leading to secretion of all classes of immunoglobulins, although primarily IgM.[498,552]

Once primary infection occurs, EBV, like other herpesviruses, is able to persist in a latent state in a human host throughout that person's lifetime. This ability indicates that EBV exerts some influence on the immune response to prevent its complete eradication. With its large genome, this process of immune system evasion is carried out primarily through the coding of functional homologues of many cellular factors that are involved in cell cycle regulation, signal transduction, and inhibition of programmed cell death (apoptosis). For example, the EBNA-1 protein contains a spacer region consisting of multiple Gly-Ala repeats that inhibit protein processing and major histocompatibility complex class I recognition of cells expressing EBNA-1.[317] Another viral protein (BARF1) blocks the receptor for colony-stimulating factor type 1, which normally stimulates secretion of antiviral factors such as interferon-α (IFN-α) through interaction with monocytes.[81] In addition, one crucial EBV protein, LMP-1, upregulates certain antiapoptosis factors, allowing prolonged survival of cells.[564]

Epstein-Barr Virus–Associated Tumors

In normal hosts, cellular immune responses are adequate for control and sequestration of EBV-infected cells. However, cellular immune deficiency may allow uncontrolled proliferation of EBV-infected B cells to occur during primary or reactivated (recrudescent) EBV infection. Such an excessive EBV-associated production of B cells may be histologically pleomorphic (such as B-cell lymphoproliferative diseases) or relatively uniform (monomorphic, such as B-cell lymphomas). In organ transplant recipients, no consistent chromosomal translocations are associated with the lymphomas. Many of these lesions regress once immunosuppressive therapy initiated after transplantation is withdrawn.[562] In rare, severe cases, B cells harboring EBV DNA and expressing EBNA may become disseminated throughout the body as plasmacytoid cells visible on peripheral blood smears and as B-lymphoid cells potentially invading all organs of the body. Life-threatening EBV infections also may be correlated with an overly strong virus-induced T-cell proliferation that might cause autoaggressive activity, producing hypogammaglobulinemia or other major organ dysfunctions.[33]

The pathogenesis of EBV-associated malignant disorders in some settings may be multifactorial and involve a mixture of virologic, genetic, and environmental factors. NPC, which occurs predominantly in a specific geographic locale, has been linked etiologically with

EBV.[209,217] The identification of epithelial cells as potential targets for EBV infection, thereby allowing a lytic (productive) infection, has strengthened this relationship.[470] Further studies have revealed that NPC is a monoclonal proliferation that develops subsequent to EBV infection, with EBV gene products required for tumor growth.[393] However, NPC also clearly has a genetic association, inasmuch as strong linkage to a specific HLA type exists.[310] Furthermore, early EBV gene expression can affect profoundly the growth of infected cells, with full malignant potential reached when mutations occur on chromosome 3 or 9 (presumably affecting tumor suppressor genes).[231,232] These mutations possibly result from adverse environmental conditions (e.g., exposure to chemical carcinogens, such as the volatile nitrosamines and polycyclic hydrocarbons in salted fish).[255]

The EBV genome and expression of EBNA-1 are present in more than 95 percent of BL cells derived from African patients with BL (endemic BL), with the genome existing as circular episomes. In contrast, only 15 to 30 percent of cases of nonendemic (or sporadic) BL occurring in Europe and the United States contain EBV DNA.[235,573] On the other hand, EBV is present in more than 95 percent of primary lymphomas of the central nervous system (CNS) in patients with AIDS.[333] BL cells, but not the lymphoid cells found in IM, exhibit characteristic chromosomal alterations associated with enhanced malignant potential. Approximately 90 percent of BL tumors exhibit a reciprocal translocation involving the long arms of chromosomes 8 and 14, t(8;14); most of the remainder have t(8;2) and t(8;22).[287,445] These translocations place the c-*myc* oncogene under the control of an immunoglobulin promoter,[95,509] which results in transcriptional deregulation and overexpression of the c-*myc* oncogene.[90,306] Malaria is well known to cause chronic B-cell stimulation, providing enhanced opportunities for c-*myc* translocations within germinal centers of lymphatic tissue. Healthy children living in areas with holoendemic malaria may have high viral loads of EBV in peripheral blood, with acute malaria further augmenting the viral load[561] and antimalaria treatment subsequently reducing the EBV load in the peripheral blood.[108] Therefore, the evolution of endemic BL appears to be a multistep process involving EBV infection, malaria-induced B-cell proliferation, c-*myc* gene rearrangement and activation, and probably other elements.[99,100,286,378,463]

PTLD may develop in organ and bone marrow transplant recipients during the intense immunosuppression that occurs after placement of the graft. PTLDs span a spectrum of lymphoproliferation from polyclonal disease to monoclonal, monomorphic disease that often is difficult to distinguish from typical malignant lymphomas developing in patients with intact immune systems. No proof exists that an orderly progression leading to malignant lymphoma occurs; however, one model for the pathogenesis of PTLD proposes that defective immune surveillance after transplantation allows polyclonal proliferation of EBV-infected cells displaying a type III latency pattern (similar to that observed in IM).[82] Subsequently, genetic mutations at various loci (e.g., c-*myc*, p53) may allow progression to full malignant lymphoma to occur.[101]

HISTOPATHOLOGY

Infectious Mononucleosis[90,162,500]

Because IM typically is benign and the diagnosis is based primarily on clinical and serologic findings, histopathologic examination of tissues seldom is required.[92] However, histopathologic information is available on some tissues (e.g., lymph nodes, tonsils, spleen) from unusual cases and from patients requiring surgery.[517] For patients in whom lymphoproliferative disease and other serious manifestations of EBV infection develop, a larger amount of information is available from a broader range of tissues.[359]

Lymph nodes are enlarged diffusely during acute IM. On histologic examination, active lymphoid follicles are noted, with lymphoid proliferation extending to the sinuses, blood vessels, trabecula, and capsule.[359] The capsule remains intact despite substantial hyperplasia. The lymphoid response consists primarily of T and B immunoblasts, typically with a pleomorphic pattern and frequent mitoses indicative of rapid cell turnover.[517] Other cells identifiable in lymph node tissues include a substantial number of small lymphocytes, large atypical lymphocytes, plasma cells, histiocytes, and eosinophils. Micronecrosis may be present, although it is less extensive than that observed with herpes lymphadenitis. Tonsillar tissue also contains an active lymphoproliferative response but with more prominent follicles and extensive necrosis.

The spleen is enlarged two to three times its normal weight during acute IM, primarily as a result of hyperplasia of the red pulp. Like in the lymph nodes, the cellularity is principally from immunoblasts with substantial pleomorphism. Hemorrhage, primarily subcapsular in location, is identified commonly. The liver typically shows minimal disease; infiltration by lymphocytes and monocytes occurs principally in the portal areas, and possibly minor degenerative changes take place in hepatocytes. Bone marrow may appear relatively normal during IM, but some series have reported hypercellularity and small granulomas.[92] From the relatively few cases of CNS disease associated with EBV infection, histopathology reveals lymphocytic infiltration of the meninges.[9] Less common findings include demyelination, degeneration, focal hemorrhage, congestion, and edema.

Epstein-Barr Virus–Associated Malignant Diseases

The most common form of non-Hodgkin lymphoma (NHL) is BL, which consists of sheets of small noncleaved cells that are histologically uniform. Most arise from a single infected cell (monoclonality). The majority of CNS NHL tumors display large-cell morphology, with virtually all containing monoclonal EBV DNA. In PTLD, a wide range of histologic findings may be noted. At one extreme, one finds benign lymphoid hyperplasia with normal tissue architecture and a pleomorphic response arising from numerous infected cells (polyclonality). At the other end is observed frank malignant lymphoma.[88]

HD is unique among cancers as less than 1 percent of cells within the tumor are actually neoplastic.[272] HD tissues are characterized by the presence of diffuse inflammatory cell infiltrates admixed with a low level of neoplastic cells: classic Reed-Sternberg cells and mononuclear Hodgkin cells (referred to collectively as H-RS cells). Reed-Sternberg cells are large (15 to 45 μm), multinucleated cells demonstrated to derive from germinal center–derived B cells.[291] These cells exhibit strongly stained nucleoli surrounded by a characteristic clear area resembling a halo. The World Health Organization classification system for HD has been revised,[246] and two main subgroups now are defined: nodular lymphocytic-predominant HD and classic HD. Within classic HD are four distinctive histologic categories based on the predominant cell type and characteristics of the background cellularity: (1) lymphocyte rich, (2) nodular sclerosis, (3) mixed cellularity, and (4) lymphocyte depleted. In Western countries, EBV can be identified in approximately 40 percent of HD tissue specimens; mixed cellularity and lymphocyte-depleted types are associated most strongly with EBV. Children most commonly develop the nodular sclerosing variety.

Of the three histopathologic categories of epithelial tumors in the nasopharynx, the most common form in children is the undifferentiated variety, which is associated most strongly with EBV.[24] Examination of these tumors reveals undifferentiated squamous cells, with substantial infiltration by lymphocytes. Malignant cells consistently contain multiple copies of monoclonal EBV DNA within episomes, and several EBV proteins are expressed.

Other Epstein-Barr Virus–Associated Diseases

The tissues involved in hemophagocytic lymphohistiocytosis typically include the bone marrow, spleen, liver, and lymph nodes, but the skin or brain may be affected as well.[137] In the bone marrow, hypocellularity often is noted. Activated macrophages (or histiocytes) appearing "stuffed" are observed engulfing all bone marrow cellular elements or their precursors or fragments, including erythrocytes, leukocytes, and platelets.[137,431,548]

Tissues affected by oral hairy leukoplakia (predominantly in adult patients with AIDS)[117] reveal keratin or parakeratin projections, mild hyperparakeratosis and acanthosis, ballooning and hyperplasia of the prickle cell layer, and only a sparse inflammatory cell infiltrate in the subepithelial connective tissue.[172] The principal histologic findings in pulmonary tissue from children infected with human immunodeficiency virus (HIV) and having lymphocytic interstitial pneumonitis are lymphoid nodules and diffuse infiltration of the alveolar septa and peribronchiolar regions by lymphocytic cells, including lymphocytes, plasma cells, plasmacytoid lymphocytes, and immunoblasts.[17] Some lymphoid nodules may be observed as well. The infiltrating lymphocytes consist of B cells and T cells.[264] Necrosis is not observed, and blood vessels are not affected.

EPIDEMIOLOGY

Seroprevalence

Epidemiologic studies of EBV were stimulated by development of reagents for detection of specific anti-EBV antibodies in serum in the mid-1960s. Specifically, tests detecting antibodies to VCA (long-lasting, early in infection) and EA (short duration, early in infection) were used. Henle and Henle,[204] using an immunofluorescence method, first noted a high prevalence of EBV VCA antibodies (100%) in patients with BL, but they also discovered a relatively high prevalence (85%) in normal adults. Subsequent studies in American[156,206,409,489,490] and British[401] populations have established that 80 to 95 percent of adults have serologic evidence of past EBV infection, with most infections occurring during infancy and childhood.

The age at initial (primary) infection varies markedly in different cultural and socioeconomic settings, a fact that has great pertinence to manifestations of disease associated with primary infection. In developing countries, EBV infection generally occurs at an early age; 80 to 100 percent of children become infected by the time they reach 3 to 6 years of age. In these settings, most children with primary EBV infection have clinically silent or mild disease.[38,138,472,490] In privileged communities and in industrialized countries, primary infection with EBV commonly occurs later in life. In these settings and for reasons that are unclear, primary infection in older age groups, for example, individuals between 10 and 30 years of age, is more likely to induce clinical symptoms, most often a mononucleosis syndrome.[68] An IM case rate of 50 to 75 percent associated with primary EBV infection was documented in U.S. college students.[375] An unexpectedly high rate of IM also has been noted with eventual development of primary EBV infection in siblings of a pediatric case of IM.[496]

Incidence

The incidence of IM from population-based studies ranges between 50 and 100 cases per 100,000 population.[126,200,202] These studies indicate that the highest incidence rates for IM occur in the age group of 15 to 19 years. Although two reports have described a modest seasonal change for IM,[180,200] most studies have indicated no seasonal predilection. IM consistently has developed at a higher rate in persons of white race than in other ethnic groups.[200] In one study, IM developed in males at a rate slightly higher than that in females.[202]

Viral Shedding

The initial indication that EBV is shed in oropharyngeal secretions came from Chang and Golden[65,69] in 1971 when they identified a "leukocyte transforming agent" in throat washings from four of eight adults with IM. Although EBV was suspected, specific laboratory tests could not confirm it.[166] Other investigators using more specific identification methods clearly established EBV as the leukocyte transforming agent.[158,328,356,376] Subsequent

studies in healthy populations have indicated the following: (1) most children and adults with acute IM shed EBV in their oropharynx, (2) between 6 and 20 percent of the general population is shedding EBV in the oropharynx at any given point of time, (3) oropharyngeal shedding may be intermittent or continuous, and (4) high concentrations of EBV in oropharyngeal secretions are associated with high concentrations of EBV in B lymphocytes in the peripheral blood but not with concentrations of EBV-specific serum antibodies.

In addition to the oropharynx, EBV DNA may be found in the urine of persons during and for several months after an episode of IM.[297] Shedding of EBV also has been reported in the uterine cervix,[471,512] the male reproductive tract,[243,512] and breast milk.[265]

Transmission

Common Modes of Transmission

Reports in the first half of the 20th century, before widespread acceptance and use of the heterophil antibody test, suggested the occurrence of epidemics of IM.[189,380,515] However, researchers generally thought that the criteria used in most of those reports to establish the diagnosis of IM were inadequate to convince one that the outbreaks were indeed associated with EBV.[220] Although some success was reported for transmission of human EBV infections to certain primate species,[258] attempts to experimentally infect humans with EBV collected from the oropharyngeal secretions, blood, urine, and feces of patients with IM generally failed.[123,124,373,478] These experiments, conducted before development of specific EBV antibody tests, presumably were unsuccessful because most experimental subjects were immune as a result of having had a previous EBV infection.

Intimate sharing of oral secretions is thought to play a major role in the transmission of EBV.[125,220] The fact that EBV infection is extremely common worldwide, especially in underdeveloped regions, suggests that the virus is spread relatively efficiently in the general population. Surprisingly, outbreaks of EBV infection are uncommon events. However, transmission of EBV, even among close contacts of a person with acute EBV infection, may occur slowly. Studies of families of index cases of IM have indicated that EBV is not transmitted efficiently.[67,141,202] Furthermore, Chang[67] reported a lack of EBV transmission from a man with IM to his EBV-seronegative wife, even after 16 months of follow-up. In addition, data from another family study indicated that after the index IM episode, EBV antibodies (seroconversion) developed in only 35 percent of the nonimmune sibling contacts after an average observation period of 5.6 contact months.[496] Nonetheless, this same study also noted that the eventual seroconversion event in siblings was more likely to be associated with an IM episode than would be expected in the general population.[496] The complexity of EBV transmission and induction of IM is suggested further by the finding of multiple strains and variability of strains in distinct body compartments of individuals with primary EBV infections.[468]

Evidence has shown that EBV replicates in oropharyngeal epithelial cells[470]; subsequent infection of B cells possibly occurs as a result of contact with these epithelial cells.[4] Further studies indicate that latent and productive EBV infection occurs in lymphoid cells on the surface of the tonsillar epithelium and within the crypt, but not in epithelial cells.[10] Thus, transmission of EBV from person to person may be due to transfer of virus from persistently infected EBV lymphoid cells; EBV-infected epithelial cells may not be required for this phenomenon.[377,557] The incubation period for typical EBV-associated IM is imprecise but is estimated at 30 to 50 days.[141,220]

Transmission via Blood Products or Transplanted Organs

Transmission of EBV via blood transfusion has been reported,* but it occurs much less commonly than does transmission of CMV. High levels of immunity, transfer of neutralizing antibodies during transfusion, and limited survival of B cells may account for the rarity of this occurrence.[211] In transplant recipients, EBV-positive donor organs may transmit EBV to the recipient.[63,69,197]

Intrauterine and Perinatal Transmission

Because most females reaching child-bearing age already have been infected with EBV, primary infections during pregnancy occur infrequently.[140,237,303] Therefore, the risk of fetal transmission is difficult to study. One prospective study of primary infections occurring during pregnancy (silent or symptomatic) indicated no adverse fetal outcomes and, when studied, no viral transmission to the fetus.[139] Moreover, Chang and colleagues[66,70] could find only one EBV-infected specimen among 2696 samples of cord blood lymphocytes. On the other hand, case reports suggest that rare instances of intrauterine transmission may occur.[51,165,261] The significance of one report noting EBV DNA in breast milk of approximately 50 percent of healthy women is unclear.[265]

Sexual Transmission

Detection of EBV in genital ulcers,[193,411] the uterine cervix,[471] and the male reproductive tract[243] raises the possibility of venereal transmission. Additional epidemiologic findings suggest that EBV transmission and onset of IM can be correlated with sexual intercourse or closely associated behaviors.[89]

NONMALIGNANT CLINICAL SYNDROMES ASSOCIATED WITH EBV INFECTION

Silent, Nonspecific Infections

Similar to other lymphotropic human herpesvirus infections, primary EBV infection in children typically is silent but may result in mild clinical symptoms. Nonspecific clinical symptoms may include prolonged low-grade

*References 2, 157, 208, 220, 351, 507, 557.

fever with or without lymphadenopathy, cough, rhinorrhea, and pharyngitis.

Infectious Mononucleosis

The signs and symptoms of classic IM* develop in most adolescents and adults, as well as in some young children, when they experience a primary (initial) EBV infection. Factors determining an asymptomatic versus symptomatic response to EBV infection are largely unknown. Adults developing IM may have an exaggerated, pathologic T-cell response to primary EBV infection. The degree of viremia does not appear to be related to symptoms, with EBV viral loads in blood from symptomatic subjects being comparable to those undergoing silent EBV infection.[465]

Prodrome

In most persons with IM, a prodrome of 2 to 5 days develops during the end of the incubation period. Prodromal symptoms typically are mild and may consist of malaise, fatigue, and possibly fever. At this stage, differentiation of IM from other viral infections is difficult.

Acute Phase

The prodrome is followed by the classic clinical features of IM (i.e., fever, sore throat, malaise, and fatigue), and physical examination reveals lymphadenopathy and tonsillopharyngitis (Table 159-1). The temperature ranges from 38° C (100.4° F) to 40.5° C (104.9° F) (usually <39° C [102.2° F]); the fever usually begins abruptly, is more prominent in the afternoon and evening, and persists for 1 to 2 weeks. On occasion, the fever may last 4 to 5 weeks. Lymphadenopathy occurs in more than 90 percent of children and adults and typically involves the anterior and posterior cervical lymph nodes (Fig. 159-1). Affected nodes are moderately enlarged in a symmetric manner. However, generalized lymphadenopathy also is characteristic and involves the occipital, supraclavicular, axillary, epitrochlear, and inguinal chains. Like with other causes of viral lymphadenitis, the lymph nodes in patients with IM may be slightly tender, but they generally are nontender, nonerythematous, and discrete. Lymphadenopathy is most prominent during weeks 2 to 4 of the illness. Tonsillopharyngitis develops during the first week of illness and usually resolves abruptly the next week. Although mild symptoms occur in some patients, most have substantial symptoms. Exudative pharyngitis, similar to that found with *Streptococcus pyogenes* pharyngitis, occurs in approximately half of patients (Fig. 159-2). *S. pyogenes* is present in the posterior pharyngeal region of 5 percent of patients with IM and probably represents carriage rather than simultaneous bacterial tonsillopharyngitis.

Splenomegaly occurs in approximately 50 percent of patients with IM but more frequently in younger children. Usually only the tip of the spleen is palpable, with maximal size developing by the end of the second week

of illness. The splenomegaly typically resolves by the third or fourth week. Hepatomegaly occurs in approximately 60 percent of young children with IM and less commonly in older age groups. However, silent inflammation of the liver is a common finding.[229] Cough and rhinitis are noted frequently in young children with IM, perhaps as a result of other concurrent viral infections. Rash (unassociated with antibiotic administration) develops in less than 15 percent of adults with IM but occurs more commonly in children and adolescents (18% to 34%).[494] The strong correlation in young adults between the administration of ampicillin and the subsequent development of a rash is not observed in children with IM, possibly overshadowed by the overall increased incidence of cutaneous manifestations in children with IM (see Complications of Infectious Mononucleosis for a detailed discussion of rashes associated with IM). Children are more likely than are adults to have abdominal pain, failure to thrive, otitis media, and recurrent tonsillopharyngitis preceding or following IM.[494] A palatal enanthem is present in approximately a third of adults, but it is a nonspecific finding. Eyelid edema also is described in up to a third of adults but occurs less commonly (15%) in children.[494]

Resolution Phase

The acute phase of IM lasts several days to 3 to 4 weeks, with gradual and uneventful resolution. On occasion, biphasic illness is observed, with recrudescence of acute symptoms after significant improvement. Organomegaly may persist for 1 to 3 months. The severe fatigue usually resolves within 3 to 4 weeks, but several months may be required for persons with IM to fully resume their preillness activity levels. There is evidence, albeit minimal, suggesting that subsequent fatigue-like syndromes in patients with IM may be related to (or predicted by) the presence of preexisting lower physical fitness or prolonged bed rest during convalescence, whereas mood disorders are more related to premorbid psychiatric history.[543]

Infectious Mononucleosis in Young Children

Increasing numbers of EBV-IM or IM-like illness are being reported in very young children, usually accompanied by compatible EBV-specific laboratory testing.* Young children may have less intense EBV-specific serologic responses or not yield these immune responses until later in the disease course. EBV genomic testing by quantitative polymerase chain reaction (PCR) of peripheral blood mononuclear cells and plasma has been suggested as a laboratory diagnostic aid in some cases.[73]

Disseminated EBV Infection in X-Linked Lymphoproliferative Disease

Overwhelming primary EBV infection, seen rarely in immunocompetent patients, occurs more commonly in children with certain primary immunodeficiency disorders, most notably boys with X-linked lymphoproliferative disease (XLP).[417,488] These patients typically first present with features consistent with IM, but fulminant disease leading to death subsequently develops. Widespread, uncontrolled lymphoproliferation is found at autopsy, and causes of death include acute hemorrhage, meningoencephalitis, secondary bacterial infection, and liver failure.[364] Survivors usually have hypogammaglobulinemia, and B-cell lymphomas may develop later. XLP is associated with the deletion or mutation of a specific gene (SLAM-associated protein) located in the chromosomal Xq25 region, which is involved in key cellular

signaling pathways for immune responses[80,372,455]; absence of this functional protein permits overwhelming and usually fatal infection from a primary EBV infection.

Hemophagocytic Lymphohistiocytosis

Hemophagocytosis, first described in 1939, is a pathologic condition demonstrating engulfment of bone marrow cellular elements (erythrocytes, leukocytes, platelets, and their precursors) by activated macrophages (Fig. 159-3). Hemophagocytic lymphohistiocytosis (HLH, also called hemophagocytic syndrome) is characterized primarily by fever, pancytopenia, splenomegaly, and hemophagocytosis in lymphoreticular tissue (bone marrow, spleen, and lymph nodes). Since the initial description of its association with viral infections in 1979,[431] numerous viral infections, including EBV, have been linked with HLH.[388,424] Hereditary forms of HLH exist, most prominently those occurring in children with XLP (see preceding section).[364] A disseminated form of EBV infection with features of HLH may develop in these patients; most other cases are sporadic. In contrast to IM, which involves infection of B cells, primary infection in patients with sporadic HLH results in an EBV-driven T-cell proliferation with proinflammatory cytokines playing a central pathogenetic role.[250] Untreated EBV-associated HLH carries a high mortality rate.

Chronic Active Disease

Although first described in 1978,[529] chronic active Epstein-Barr virus (CAEBV) infection is not as well characterized as are other EBV-associated diseases.[149] It shares with HLH the central theme of infection and proliferation of non-B cells. CAEBV infection occurs more commonly in Japan,[282] with children affected more frequently than adults. Two forms of the disease have been described, one involving EBV-infected T cells and the other affecting NK cells.[283] Patients with the more severe form can be considered to have a chronic version of HLH, with similar symptoms and a uniformly poor prognosis. After having a typical IM-like illness, these patients develop persistent infection of their peripheral T cells ($CD4^+$, $CD8^+$, or both) and do not recover fully. Continuous or intermittent signs and symptoms, persisting for 3 months or longer, typically include fever, hepatosplenomegaly, lymphadenopathy, headache, malaise, and fatigue.[462,545,546] More severe cases display neurologic disease (e.g., encephalitis), malignant disease (e.g., lymphoma or leukemia), hepatic failure, hematologic disease (e.g., hemophagocytosis), and disease localized to other organs (e.g., myocarditis, pneumonitis).[282] One distinctive characteristic of these patients is the extremely high antibody titers against EBV replicative antigens, including VCA and EA, and low or absent responses to EBNA. Poor prognostic factors include older age and high EBV viral loads.[282] Some cases may be related to mutations in the perforin gene.[262,270] Clonal expansion of EBV-infected T cells probably plays a central role in disease pathogenesis.[282] A second form of the disease, described principally in Japanese patients, is characterized by milder IM symptoms, less extreme EBV serologic abnormalities, granular lymphocytosis, and high IgE levels.[283] Interestingly, these patients also typically develop pronounced skin reactions in response to mosquito bites. Large expansions of EBV-infected, CD56-positive NK cells are observed in peripheral blood and in the skin reactions. CAEBV infection should not be confused with chronic fatigue disorder, which has no clear association with EBV.

Other Diseases

EBV has been linked with various autoimmune disorders in children and adults, primarily on the basis of seroepidemiologic information. These disorders include rheumatoid arthritis,[57] systemic lupus erythematosus,[248,349] and multiple sclerosis.[5] Further careful studies must be conducted to substantiate these early reports of an etiologic relationship with EBV.

COMPLICATIONS OF INFECTIOUS MONONUCLEOSIS

Acute EBV infection in a healthy child or adolescent, regardless of whether it is associated with typical IM, rarely is complicated by serious illness.[492] The most frequent complications, exanthems and mild hepatitis, more appropriately are considered part of the normal spectrum of disease.[290] More serious complications involving major organs have been reported regularly since IM first was described as a distinct clinical entity, but they remain rare (for review, see elsewhere[6,253,400,494]). Most complications, including the more severe ones, are transient.

In one prospective study,[494] significant complications involving mainly the pulmonary, neurologic, and hematologic systems were noted in approximately 20 percent of children with IM. Thrombocytopenia with

hemorrhagic manifestations, severe airway obstruction, and neurologic complications developed in children with IM more frequently than in adults; jaundice occurred less frequently.

Exanthems

Ampicillin Rash. Historically, patients with IM were treated frequently with antibiotics, primarily for suspected streptococcal pharyngitis or bacterial lymphadenitis. Soon after the release of ampicillin, reports linked the antibiotic with the occurrence of exanthems in patients with IM. Two large case series have indicated that administration of ampicillin (or amoxicillin) precipitates an exanthem in most (95% to 100%) adolescents and adults with EBV-associated IM[391,415]; it is less common in children with IM.[494] This phenomenon has become known as the ampicillin rash associated with IM. The rash usually develops 5 to 10 days after treatment is initiated and resolves within a few days of discontinuation. Characteristically, the cutaneous lesions are maculopapular and pruritic and involve the trunk, face, and extremities (Fig. 159-4).[391] A rash also may develop in patients with IM treated with other β-lactam antibiotics, but such rashes do not represent hypersensitivity reactions.

Other Exanthems. An exanthem will develop in approximately 3 to 15 percent of persons with IM not treated with β-lactam antibiotics.* These rashes are maculopapular but can be urticarial, scarlatiniform, or erythema multiforme–like. Erythema nodosum also has been noted.[43] Although most commonly associated with hepatitis B, some cases of Gianotti-Crosti syndrome (papular acrodermatitis of childhood) also have been related to primary EBV infection.[225]

Cardiac

Mild electrocardiographic abnormalities (mostly nonspecific ST and T wave changes) have been observed in 6 to 16 percent of adults with IM.[113,222] Abnormalities usually are noted during the second or third week of illness and disappear by the fourth week, but they may persist longer. A case of myocarditis heralding typical IM has been noted in a young adult.[531] Serious cardiac complications occur extremely rarely.[145]

Hematologic

Hemolytic Anemia. Hemolytic anemia occurs in 1 to 3 percent of patients with IM,[223,494] and many cases have been reported in children with previously unrecognized hemoglobinopathies. The anemia typically develops during the second or third week of illness and resolves in 1 to 2 weeks. Corticosteroid therapy may hasten resolution.[155]

Aplastic Anemia. This anemia is a rare complication of IM, with only scattered case reports in the literature.[175,302,524] Steroids have been beneficial,[169] but bone marrow transplantation has been necessary in some cases.[318] Fatalities have been recorded, usually in association with pancytopenia.[1,524]

Thrombocytopenia. Thrombocytopenia occurs in 25 to 50 percent of patients with IM[59,60] and probably is immune mediated. Platelet counts usually return to normal levels 4 to 6 weeks after the onset of illness. Severe thrombocytopenia (platelet counts $<20 \times 10^3/mm^3$) occurs rarely, with fewer than 40 cases identified in one review.[405] These authors noted a complication rate of 27 percent and a mortality rate of 5 percent associated

*References 27, 221, 259, 343, 421, 494.

with severe thrombocytopenia. Case reports have suggested beneficial effects of corticosteroids[322,504] or intravenous immune globulin[112] for severe, life-threatening thrombocytopenia.

Neutropenia. Mild to moderate neutropenia occurs frequently during IM.[58,61] Neutrophil counts typically reach their lowest values during the third and fourth weeks of illness but may persist for another month or more. Although severe neutropenia (absolute neutrophil count <200) and agranulocytosis are rare events, with patients recovering uneventfully, death from overwhelming bacterial infection has been reported.[370] Antineutrophil antibodies elicited during EBV-induced polyclonal antibody stimulation probably are the source.[456]

Pancytopenia. Pancytopenia has been reported to develop in a small number of children and adults with IM.[293] Fatalities attributable to overwhelming bacterial infection have occurred.[247,524]

Spleen

Detectable splenomegaly develops in up to 50 percent of patients with IM; one study demonstrated splenic enlargement by ultrasound examination in 100 percent of patients hospitalized with IM.[107] Patients with a palpable spleen are at risk for having spontaneous rupture. In the United States, spontaneous rupture of the spleen occurs in an estimated 1 in every 1000 adults with IM[130,337]; the rate of splenic rupture in children is unknown but probably is lower. Rupture typically occurs during the first to third week of illness and is heralded by abdominal pain. Signs of hypovolemia occur frequently and include orthostasis, tachycardia, and syncope. Pain in the left shoulder (Kehr sign),[331] caused by diaphragmatic irritation from blood, is observed in approximately 50 percent of patients with splenic rupture; right shoulder and subscapular pain may develop as well.[452] Splenic abscess has been described in a child with IM.[75]

To reduce the risk of splenic rupture, physicians customarily caution patients against engaging in strenuous physical activity and contact sports during recovery from the acute illness and for the period of significant organomegaly.[448,535] Recommendations for reduced activity vary between 3 weeks and 6 months. In one review, the lack of evidence-based information about the timing of return to activity for athletes is acknowledged, and physicians are discouraged from making decisions on the basis of a single parameter.[535] Instead, individualized decisions must be made. In general, if the patient is asymptomatic without a palpable liver or spleen, a gradual return to pre-IM levels of activity probably is safe. Imaging procedures (e.g., computed tomography or ultrasonography) generally are not cost-effective or accurate in determining the timing for normal activity, but they may be considered for athletes desiring to return to play early and for those with ambivalent examination findings.

Most cases of splenic rupture require emergency splenectomy.[130] However, in an effort to maintain the patient's hematologic and immunologic competence, practical management of splenic rupture is evolving. At some institutions, selected patients with splenic rupture who meet certain requirements, including hemodynamic stability with low transfusion requirements and a normal level of consciousness, may be managed with medical therapy[22] or endovascular interventional methods[48] instead of traditional splenectomy.

Gastrointestinal Tract

Liver. Mild to moderate, subclinical inflammation of the liver occurs in more than 90 percent of patients with IM.[229] Rarely, more serious cases of hepatic disease, including fulminant hepatic failure in children, have been described.* Chronic hepatitis also has been reported.[506]

Other. Other gastrointestinal diseases purportedly associated with IM include pancreatitis, gastritis, typhlitis, and cholecystitis.†

Neurologic

Acute neurologic disorders[85,466] develop in 1 to 5 percent of persons with IM.[36,221,466] Neurologic complications usually occur at the height of the typical manifestations of IM, but they also may develop during the resolution phase. In addition, some reports document neurologic disease as a heralding event, before the development of typical IM, or even as the sole manifestation of EBV infection, especially in children.[45,104,106,121,363] The most common neurologic complications include those occurring in the CNS, such as aseptic meningitis, meningoencephalitis, and encephalitis; however, other central and peripheral neurologic complications have been described. The pathophysiologic process of CNS manifestations is not well established. Possible mechanisms include direct viral invasion, immunologic mechanisms, and inflammation.

Encephalitis and Aseptic Meningitis. EBV frequently affects the CNS, causing cerebrospinal fluid (CSF) abnormalities and electroencephalographic abnormalities, yet most patients exhibit no symptoms.[398] In two large series of patients with encephalitis, EBV was responsible for 2 to 5 percent of cases,[275,288] and EBV caused 8 percent of cases of focal encephalitis.[544] Clinical findings in EBV encephalitis include fever, headache, vomiting, seizures, alteration in mental status, irritability, disorientation, lethargy, and, occasionally, a comatose state.[104] Symptoms suggestive of schizophrenia, such as delusions, hallucinations, and extreme agitation, are seen occasionally. Patients with aseptic meningitis typically complain of a stiff neck, headache, fever, and vomiting. Symptoms of IM occur uncommonly in children developing EBV encephalitis. Typical CSF findings in children with EBV encephalitis include mild to moderate pleocytosis (lymphocytic predominance) in 50 percent, mildly elevated protein levels in half of cases, and normal glucose concentration.[106] EBV antibodies, EBV DNA, and even EBV itself have been identified in the CSF or brain tissue of persons with EBV-associated neurologic complications.[192,238,260,396] Some reports suggest that the immune dysregulation caused by primary EBV infection may act as a triggering mechanism for the development of measles-associated subacute sclerosing panencephalitis.[132,224] Because typical IM symptoms seldom

*References 103, 148, 199, 290, 330, 334, 341.
†References 201, 290, 321, 390, 464, 568.

occur in children with EBV encephalitis and clinical findings are not specific, EBV should be considered a possible etiology for any child with acute encephalitis.

Other CNS Manifestations. EBV-associated cerebellitis is a rare occurrence that develops primarily in children and young adults.[78,85,121,163] Full recovery occurs within weeks to months. Cranial nerve palsies, singly or in combination, also occur rarely; the facial nerve is involved most commonly.[353,566] Other manifestations of cranial nerve involvement include optic neuritis,[143] deafness,[121,547] and ophthalmoplegia.[450] Some cases of brain stem encephalitis[381,461] and recurrent aseptic (Mollaret) meningitis[169] have been reported.

Non-CNS Neurologic Complications. Outside the CNS, Guillain-Barré syndrome (ascending polyradiculoneuritis) is the most common complication of EBV infection.[176,177,426] Other non-CNS neurologic complications of IM include peripheral neuropathy,[115] autonomic dysfunction,[556] hemiplegia,[29] and transverse myelitis.[520]

Renal

Silent abnormalities of the urine sediment, including proteinuria and microscopic hematuria, occur commonly in patients with IM.[221,237,308] However, clinically significant renal disease is an extremely rare event. Tubulointerstitial disease and nephrotic syndrome have been observed most commonly.[42,527] Acute renal failure with and without rhabdomyolysis has been reported.[144,311,527] Some children and adolescents have developed hemolytic-uremic syndrome related to acute EBV infection.[459,467]

Respiratory Tract

Airway Obstruction. Severe airway obstruction occurs in 1 to 5 percent of children and adults with IM. Alpert and Fleisher[6] observed severe airway obstruction in a fourth of children admitted for complications of IM. Patients typically have severe tonsillopharyngitis with progressive symptoms of airway obstruction, usually in association with dysphagia and odynophagia. Airway obstruction may occur at any of several levels, including inflammation and hypertrophy in the Waldeyer ring, edema of the epiglottis and pharynx, and development of pseudomembranes in large airways.[162,185] Management of airway obstruction has included systemic corticosteroids, tonsillectomy, tracheostomy, and nasopharyngeal airway placement as well as general supportive measures, such as humidification and elevation of the head of the bed.[477,549] Nonsurgical management, including the systemic administration of steroids, usually is beneficial, although tonsillectomy may be necessary in refractory cases.[477,485,549] With the widespread availability of intensive care and mechanical ventilation, mortality from this complication is much lower than previously observed.

Neck Abscesses. Cervical and peritonsillar abscesses have been described in association with IM.[55,195,257,541] This uncommon complication follows severe tonsillopharyngitis in patients with IM and typically is caused by bacteria found in the oral cavity, including alpha-hemolytic streptococci and anaerobes. Appropriate management includes administration of antibiotics and surgical drainage. Some concern exists that corticosteroid therapy of incipient airway obstruction may predispose to the development of an abscess.[55,195] On the other hand, abscesses may develop in the absence of previous corticosteroid therapy.[152,410]

Pulmonary Disease. Radiographic evidence of pulmonary infiltrates occurs in 0 to 5 percent of patients with IM,[113,298] yet significant symptoms rarely are present.[113,221,298] Some cases of IM with pulmonary disease may represent coinfection with other etiologic agents.[15,134] However, several immunocompetent adults (but few children) with acute EBV infection have been described with pulmonary disease seemingly unrelated to other organisms.[79,191,382] Typically, unilateral or bilateral interstitial infiltrates are observed, and pleural effusions may be present.[116,289] In some cases, EBV has been detected in lung tissues.[483,525] Recovery is the rule, although mechanical ventilation may be necessary.

Psychiatric

Chronic Fatigue. In the early 1980s, a chronic debilitating disorder (now designated chronic fatigue syndrome) began receiving increased publicity and purportedly was linked etiologically to EBV.[263,487] The syndrome occurs more commonly in middle-aged women and is characterized primarily by chronic debilitating fatigue as well as by low-grade fever, mild lymphadenopathy, pharyngitis, neuropsychological problems, and other symptoms. The association with EBV was drawn mainly from epidemiologic features and some abnormal EBV-specific immune responses. Variable general immunologic abnormalities have been described in some cases. However, no consistency exists in these findings, and a plausible pathogenetic association has not been demonstrated. Most experts today do not regard EBV as a major etiologic agent in the development of this syndrome, although it may play a contributory role along with other viruses (e.g., human herpesvirus 6, CMV). Variably prolonged episodes of fatigue symptoms after IM continue to be reported, particularly among young adult women and those with premorbid mood disorders.[273,402]

"Alice in Wonderland" Syndrome. This unusual syndrome, technically termed metamorphopsia, is a visual illusion manifested as a distortion in size, form, movement, or color, and it is associated most commonly with migraine headaches, epilepsy, and hallucinogenic drugs. Copperman[87] first described its association with IM in 1977, and other similar cases also have been described.[76,122,295,296] Onset may occur during or soon after resolution of the clinical IM symptoms, and it may resolve within 4 to 6 weeks. Visual evoked potentials suggest diminished cerebral perfusion in affected cases.[296]

Miscellaneous Complications

Other complications purportedly associated with IM or primary EBV infection include recurrent tonsillitis,[526] sinusitis,[491] periorbital cellulitis,[491] ocular disease,[344] acute dacryocystitis,[160] rhabdomyolysis,[386] genital ulcers,[192,193,290,411] and orchitis.[420] EBV has been implicated in the pathogenesis of advanced types of periodontal disease.[473]

MALIGNANT DISEASES ASSOCIATED WITH EPSTEIN-BARR VIRUS

Burkitt Lymphoma

Endemic BL is a rapidly progressive and fatal tumor that predominantly affects young children in central Africa and Papua New Guinea (Fig. 159-5).[54] Approximately 60 percent of African patients with BL present with jaw masses; abdominal masses are second most common.[570] Less common sites include the CNS and the eye. Non-African patients with BL are most likely to have abdominal masses initially. In some patients with BL and some with congenital or acquired immunodeficiencies (including AIDS), CNS involvement is present or eventually develops and is characterized by intracranial mass lesions of lymphomatous cells or a CSF pleocytosis consisting of malignant cells, or both.[14,570,571]

Hodgkin Disease

The association of EBV with HD is based primarily on serologic studies[315,365] and identification of EBV DNA in H-RS cells (the malignant cells characteristic of HD).[276,539] The differential incidence distribution of HD in children throughout the world corresponds with the age at first EBV infection: it increases in adolescence in developed countries and increases in early childhood in developing countries.[184,256] Virtually all cases of HD in developing countries are associated with the presence of EBV, whereas the virus is present in approximately 40 percent of patients with HD in developed countries.[277] However, in developed countries, EBV is strongly associated with HD in children younger than 10 years and in tumors displaying the mixed cellularity variant.[20,213,389] HD rarely occurs in children younger than 5 years in Western countries, but it is seen more commonly at younger ages in developing countries. The precise pathogenetic mechanisms for EBV-associated HD are being unraveled, but evidence indicates that HD is primarily a result of chronic inflammation, with EBV contributing to the overproduction of various cytokines and chemokines by H-RS cells and the surrounding inflammatory cells.[277] Patients typically have cervical or supraclavicular lymphadenopathy as well as mediastinal adenopathy (occasionally with obstructive symptoms).[233] Constitutional symptoms such as fever, night sweats, and weight loss develop in approximately a fourth of patients with HD, and these symptoms worsen the prognosis.

FIGURE 159-5 ■ African boy with Burkitt lymphoma involving the jaw. (Courtesy Dr. George Miller, Yale University.)

Nasopharyngeal Carcinoma

NPC occurs primarily among adults in southern China, but it may be seen in Greenland, Alaska, and the Mediterranean region as well; the tumor is extremely rare in Western countries.[128] In endemic regions, children younger than 16 years account for only 1 to 2 percent of all cases of NPC, whereas this proportion is higher (10%) in the United States.[240,319] Children with NPC most commonly present with a painless unilateral neck mass, nasal symptoms (congestion, epistaxis, discharge), auditory symptoms (otalgia, otitis media, hearing loss), and cranial nerve abnormalities.[24,255] At initial evaluation, children with NPC are more likely than are adults to have locoregional disease.[24,240]

Posttransplant Lymphoproliferative Disease

Children immunosuppressed for organ transplantation have an increased risk for development of EBV-related lymphoproliferative syndromes and B-cell lymphomas (collectively termed PTLD).[219,292,479] Ho and colleagues[219] reported a greater frequency of lymphoproliferative lesions in pediatric transplant recipients (4%) than in adult transplant recipients (0.8%). Pediatric organ transplant recipients are thought to have an increased risk for development of EBV-related PTLDs because, compared with adult transplant recipients, they are more likely to be seronegative for EBV at transplantation, and primary infection is more likely to progress to PTLD and other severe EBV-associated disorders.[218,219] Furthermore, among pediatric renal transplant recipients with primary EBV infection, adolescents are at a higher risk for development of PTLD and have poorer outcomes compared with younger recipients.[474] Some variability exists in the incidence of PTLD according to the specific organ transplanted. The incidence is highest in children receiving intestinal transplants (31%),[486] probably attributable to more profound immunosuppressive regimens and greater loads of lymphatic tissue in the grafts; generally lower PTLD incidences are noted in other pediatric organ transplant populations (liver: 7% to 13%; thoracic organs: 4% to 12%; kidney: 1% to 9%).[486] After human stem cell transplantation, the 10-year cumulative incidence rate for PTLD is approximately 1 percent overall.[91] Rates of PTLD are substantially higher if benign, hyperplastic cases of PTLD are included.[567]

The clinical history, physical examination findings, and confirmatory virologic laboratory testing are required to establish a diagnosis of PTLD.[230] Symptoms may be nonspecific, especially early in the course, and include fever, malaise, weight loss, abdominal symptoms (bleeding, nausea, vomiting), sore throat, swollen lymph nodes, headache, focal neurologic symptoms, and indications of graft dysfunction.[171,230] On examination, signs may include lymphadenopathy, large tonsils, hepatosplenomegaly,

pallor, subcutaneous nodules, and focal neurologic findings.[171]

Subsequent EBV-associated smooth muscle tumors (e.g., leiomyosarcomas) have been found to develop in some adolescent and young adult patients undergoing organ transplantation.[307,437]

Lymphoproliferative Disease in Other Immunodeficient Patients

Patients with a wide variety of congenital immunodeficiencies (e.g., severe combined immunodeficiency syndrome, Wiskott-Aldrich syndrome, ataxia-telangiectasia, Chédiak-Higashi syndrome, common variable immunodeficiency) as well as iatrogenically immunosuppressed patients (e.g., patients receiving cancer chemotherapy or anti–tumor necrosis factor-α monoclonal antibodies) also are at risk for development of various EBV-associated lymphoproliferative diseases and severe atypical EBV infections. One should keep in mind, however, that IM and other forms of EBV infections in immunocompromised children and adults usually run a course similar to that in immunocompetent persons; actually, even in immunosuppressed patients (and posttransplantation subjects), the majority of EBV infections are clinically silent.[210,219]

Other Malignant Diseases

Other rare lymphoproliferative diseases (B-cell and T-cell) as well as carcinomas have putative associations with EBV. The strength of these associations is variable. Pyothorax-associated lymphomas, occurring at sites of long-standing inflammation (e.g., tuberculosis), are strongly associated with EBV, with EBV identified in tumor cells in 70 to 100 percent of cases.[150] Lymphomatoid granulomatosis, seen predominantly in immunosuppressed patients, has the distinctive histopathologic finding of malignant cells surrounding blood vessels (angiocentricity). This malignant disease is considered to have a pathogenesis similar to that of PTLD, with diminished T-cell surveillance probably allowing proliferation of EBV-transformed B cells.[425] Lymphomatoid granulomatosis occurs primarily in the lung but may be found at other sites, including lymph nodes of children.[111] Plasmablastic lymphomas (extraordinarily rare in children) are unusual tumors typically found in the oral cavity of adult patients with AIDS, but they also sometimes are found in immunocompetent patients.[62] They have a strong association with EBV.

Several T-cell lymphomas are associated with EBV.[425] They include (1) angioblastic lymphadenopathy[540]; (2) enteropathy-type T-cell lymphoma (often associated with celiac disease)[555]; (3) extranodal nasal T/NK-cell lymphoma, an aggressive tumor involving the nasal or midline facial area or other non-nasal, extranodal sites[245]; and (4) aggressive NK-cell leukemia, a rapidly fatal disease heralded by an acute symptom complex that includes fever and multiorgan system failure.[245]

Gastric carcinomas are more common in Asia, but they are extremely rare in children. In adults, two types of gastric tumors are noted to be associated with EBV. Gastric adenocarcinoma is a more common tumor, but EBV is found in only approximately 10 percent of tissues. In contrast, EBV can be found in the majority of tissues from patients with gastric tumors displaying an undifferentiated (lymphoepithelioma-like) histopathologic pattern.[279] Also in Asian populations, EBV is detectable within most lymphoepithelioma-like salivary gland tumors[460] and could play an etiologic role. Considerable ongoing debate continues about the etiologic relationship of EBV with breast cancer.[301]

EPSTEIN-BARR VIRUS AND HUMAN IMMUNODEFICIENCY VIRUS

Several studies have indicated that underlying HIV infection is responsible for abnormal responses to EBV infections. These findings probably are attributable to the relative ineffectiveness of T cells from patients with AIDS in controlling EBV-infected lymphocytes.[41] In HIV-infected adults, these unusual reactions include exaggerated antibody responses to certain EBV antigens, including VCA and EA,[419] and enhanced oropharyngeal shedding of EBV.[7,133,251,376] Oropharyngeal shedding of EBV occurs more commonly in younger HIV-infected children, and children whose HIV disease progressed more rapidly had a substantially higher rate of excretion.[133,251] In another study, EBV infection developed in HIV-infected children at an earlier age and was more likely to involve hepatosplenomegaly.[397] Whether EBV contributes directly to the progression of immune deficiency in these patients continues to be a matter of conjecture, although in vitro studies do indicate that some EBV proteins (e.g., LMP, BZLF1) are able to transactivate HIV-1.[194,338]

Studies clearly have revealed that certain lymphoproliferative and other diseases develop in HIV-infected patients at rates higher than those in healthy persons. These diseases include NHL, HD, body cavity lymphoma, smooth muscle tumors, lymphocytic interstitial pneumonitis (LIP), and oral hairy leukoplakia.

NHL has remained the most common malignant disease occurring in children with AIDS[39] and is an AIDS-defining condition.[86] In the present era of highly active antiretroviral therapy (HAART), NHL also has surpassed Kaposi sarcoma as the most common malignant disease in adults.[117] In one pediatric study, approximately one third of NHL tumors contained EBV DNA.[348] Primary CNS lymphomas are extremely rare occurrences in healthy children, but they have accounted for 8 percent[348] to 23 percent[39] of NHLs in children with AIDS. Primary CNS lymphomas are linked strongly to EBV, with the virus present in virtually every case.[333] NHL invariably occurs in patients with AIDS who have profound immune suppression (e.g., $CD4^+$ concentration <200 cells/μL). Pediatric patients with AIDS and NHL typically have systemic symptoms of fever and weight loss. Signs of extranodal disease include hepatosplenomegaly, abdominal distention, jaundice, bone marrow involvement, and, rarely, CNS symptoms.[347] Although it is not an AIDS-defining condition, HD in adults with AIDS historically has occurred at rates 5 to 15 times higher than in the general

population. HD is an uncommon occurrence in children with AIDS, but it has been described.[348,413] HIV-infected patients, including children,[413] appear more likely than non–HIV-infected patients to present with disseminated disease, sometimes without obvious nodal involvement on physical examination.[406] In adults with AIDS, the incidence of HD has increased significantly in the HAART era.[117] Interestingly, HD incidence rates are higher in patients with AIDS and moderate compared with severe immune suppression, and the increased incidence is postulated possibly to be related to the inability of EBV-infected H-RS cells to recruit sufficient lymphocytes and histiocytes for their survival.[40]

Body cavity lymphoma (or primary effusion lymphoma) is a rare malignant disease that occurs almost exclusively in adult patients with AIDS, but it has been reported in children.[305] Patients typically have immunoblastic lymphomatous effusions without solid tumors in body cavities, such as the peritoneum or pleura.[367] More than 75 percent of these nonsolid tumors are associated with human herpesvirus 8; however, EBV also is identified frequently in tumor cells. EBV may play a cofactorial role in the pathogenesis of these unusual tumors.[425]

Leiomyosarcoma is an extremely rare occurrence in healthy patients,[560] but it is the second most common malignant disease in children with AIDS[346] and is an AIDS-defining condition (Category B).[86] It also has developed in solid-organ transplant recipients[307] and in patients with other types of immunodeficiency.[354] EBV may be responsible for the unusually high incidence of these smooth muscle tumors found in children with AIDS.[252,348] Leiomyosarcoma tissues from patients with AIDS have high concentrations of EBV (CD21) receptors, contain clonal (or oligoclonal) EBV DNA, and express EBERs and EBNA-1.[252,348] Leiomyosarcoma may develop in any smooth muscle tissue in patients with AIDS, but more typically it is noted first in the gastrointestinal tract and lungs.

LIP is a lymphoproliferative disease that occurs primarily in children with AIDS.[16] In the era before HAART, the incidence of LIP was 12 percent among children enrolled in a large longitudinal natural history study[167]; in the HAART era, this incidence has dropped to less than one case of LIP per 1000 person-years. Previous serologic and virologic evidence pointed to an association with EBV,[16,272,422,446] but the exact role that EBV plays in this lymphoid proliferation is unclear at present. LIP is associated with an improved prognosis for survival.[446] On radiographic examination, diffuse interstitial infiltrates are noted. The course of disease is variable. Many infections in infants are asymptomatic, and whereas some children remain stable for long periods, others may exhibit a slow but relentless progression to chronic lung disease typified by tachypnea, cough, wheezing, and hypoxemia. Advanced disease is characterized by clubbing, wasting, cor pulmonale, and bronchiectasis.

Oral hairy leukoplakia is a nonmalignant squamous cell proliferation that develops in the oropharynx of patients with AIDS. Although a common occurrence in adults with AIDS, it occurs in less than 5 percent of HIV-infected children.[335] EBV DNA and virus replication can be detected within epithelial cells,[173,476] with defective variants possible.[151] Oral hairy leukoplakia lesions are manifested as nonremovable gray or white plaques on the lateral surface of the tongue; they often have vertical corrugations and a shaggy or "hairy" appearance when dry.[458]

DIAGNOSIS OF INFECTIOUS MONONUCLEOSIS

General Laboratory Findings

Patients with IM typically have an absolute lymphocytosis (>50% lymphocytes, with total leukocytes >5000/μL), prominent atypical lymphocytes (usually >10% of total leukocytes), and a positive test result for Paul-Bunnell heterophil antibodies (positive differential heterophil). The atypical lymphocytes observed in the blood of patients with mononucleosis (Fig. 159-6) predominantly consist of activated T lymphocytes responding to the B-cell infection.[394] Although often considered a hallmark of IM, atypical lymphocytes also may be observed in association with CMV infection, toxoplasmosis, measles, mumps, roseola, rubella, drug reactions, and other conditions.[74,553]

For a typical uncomplicated case of IM, establishing a specific diagnosis of EBV infection is unnecessary; a complete blood count, differential, and heterophil antibody test are sufficient for diagnostic testing. The results of these tests are uncommonly normal early in the course of disease, and thus the tests may need to be repeated during the first 3 to 4 weeks before diagnostic results are achieved. The clinician should be aware that very young (<4 years) patients with primary EBV infection frequently have a negative heterophil test result.[493] Some studies suggest that a higher ratio (>0.35) of lymphocytes to white blood cell counts[550] or the detection of lymphatic tissue with fibrinous membranes observed by nasopharyngeal endoscopy[536] may distinguish between IM and acute bacterial tonsillitis.

Heterophil antibodies classically were measured as sheep erythrocyte agglutinins.[395] Beef, ox, and horse red blood cells also are agglutinated by the heterophil

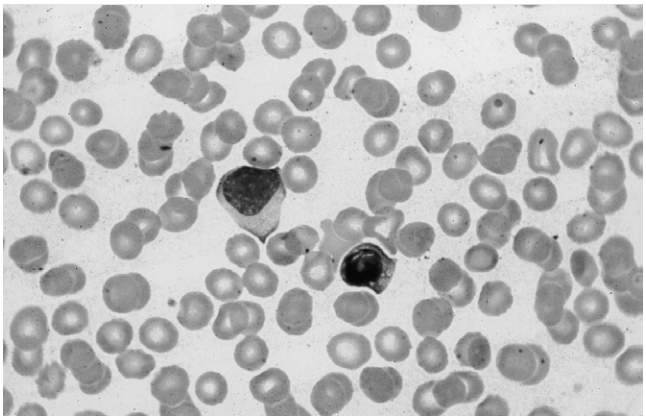

FIGURE 159-6 ■ Atypical lymphocytes in the peripheral blood of a patient with infectious mononucleosis. (Courtesy Dr. Margaret Gulley, University of North Carolina, Chapel Hill, NC.)

antibodies found in the serum of patients with IM, but these heterophil antibodies do not bind to guinea pig kidney antigen extracts. These properties of mononucleosis heterophil antibodies distinguish them from the naturally occurring Forssman heterophil antibodies and from the heterophil antibodies found in serum sickness and other conditions. Thus, traditional tests for Paul-Bunnell heterophil antibodies involve absorption of the test serum with beef or ox red blood cells (which remove Paul-Bunnell heterophil antibodies) and guinea pig extract (which does not remove them). Tests in current use (e.g., mono test, Mono-Diff, Monospot) typically use horse red blood cells, which provide a more sensitive assay than do sheep erythrocytes. However, when horse erythrocyte agglutination tests are performed, the specificity of a positive result always should be confirmed by absorption of the serum with at least guinea pig kidney extract or, preferably, with both guinea pig kidney extract and beef (or ox) red blood cells. Materials for the absorption steps are included in many but not all of the kits available commercially. Another heterophil antibody test, the beef (or ox) erythrocyte hemolysin assay, does not require absorption of the test sera but is somewhat less sensitive than is horse erythrocyte agglutination testing. Other tests[142,188,312,439] using purified forms of heterophil antigen do not seem to offer any significant advantage over the rapid slide test using horse erythrocyte agglutination.

Other laboratory tests in patients with severe mononucleosis syndromes or in those with atypical clinical manifestations may indicate involvement of major organs, but such involvement rarely is associated with severe complications (see the previous section, Complications of Infectious Mononucleosis). These laboratory abnormalities include elevated transaminase levels, mild hemolytic anemia, and neutropenia.

EBV-specific laboratory testing should be reserved for patients with an EBV-suspected disease (1) lacking a heterophil antibody response, (2) exhibiting atypical, severe manifestations, or (3) associated with significant lymphoproliferative, oncogenic, or chronic findings.[495] In most cases of EBV-associated IM episodes in immunocompetent patients, EBV-specific serology (i.e., antibody determination) is sufficient to affirm the viral-specific diagnosis. Isolation of virus from body secretions, fluids, and tissues (see later section, Virus Isolation) is labor-intensive and not widely available. Quantitation or semiquantitation of EBV-specific viral load provides some measure of activity or putative influence of the virus in a variety of EBV-associated diseases. Other laboratory methods demonstrating high concentrations of actively replicating virus or latent antigens (such as immunohistochemical methods for antigen testing or quantitative PCR) may be more useful in associating EBV infection with disease, particularly in immunocompromised patients (Table 159-2).

Epstein-Barr Virus Antibodies

The viral-specific diagnosis of EBV-associated primary infections as IM in immunocompetent individuals (and commonly in immunocompromised patients) usually requires three types of antibody analysis on acute serum: IgG to EB VCA (VCA IgG), IgM to EB VCA (VCA IgM), and IgG to EBNA (EBNA IgG).[495] (The EBNA complex is composed of six nuclear antigens or proteins, principally EBNA-1; the antibody response to the complex will herein be referred to as IgG to EBNA, or EBNA IgG.) The three EBV antibodies can be detected by commercially available immunofluorescent techniques or by various enzyme immunoassays. The need to add the determination of IgG to EB early antigen, a serologic response commonly found early in the primary infection, usually is not necessary for IM-like episodes.

Evolution of the serologic response to EBV antigens after a prototypic EBV-associated IM episode is depicted

TABLE 159-2 **Summary of Laboratory Tests for Epstein-Barr Virus (EBV)–Associated Diseases**

Detection of	Test	Purpose
Antibodies	Heterophil antibody	Detect heterophil antibodies indicating infectious mononucleosis (more reliable in patients older than 4 years)
	EBV antibodies	Measure antibody response to viral proteins in serum samples; distinguish acute from remote infection
EBV DNA and RNA	Southern blot	Assess clonality of lesions with respect to EBV DNA structure; distinguish latent from replicative infection
	In situ hybridization	
	RNA (EBERs)	Identify EBER transcripts in specific cell types within histologic lesions
	DNA	Identify EBV DNA in specific cell types within histologic lesions
	PCR	Detect and quantitate EBV DNA in blood or CSF to diagnose and monitor disease
EBV proteins	Immunohistochemistry	Identify EBV protein expression in specific cell types within histologic lesions; distinguish latent from replicative infection on the basis of expression profiles
EBV	Virus culture	Detect infectious virions or latently infected B cells; impractical for routine clinical use
	Electron microscopy	Identify whole virions representing replicative infection; impractical for routine clinical use

CSF, cerebrospinal fluid; EBER, EBV-encoded RNA; PCR, polymerase chain reaction.
Modified from Gulley ML: Molecular diagnosis of Epstein-Barr virus–related diseases. *J Mol Diagn* 2001;**3**:1-10.

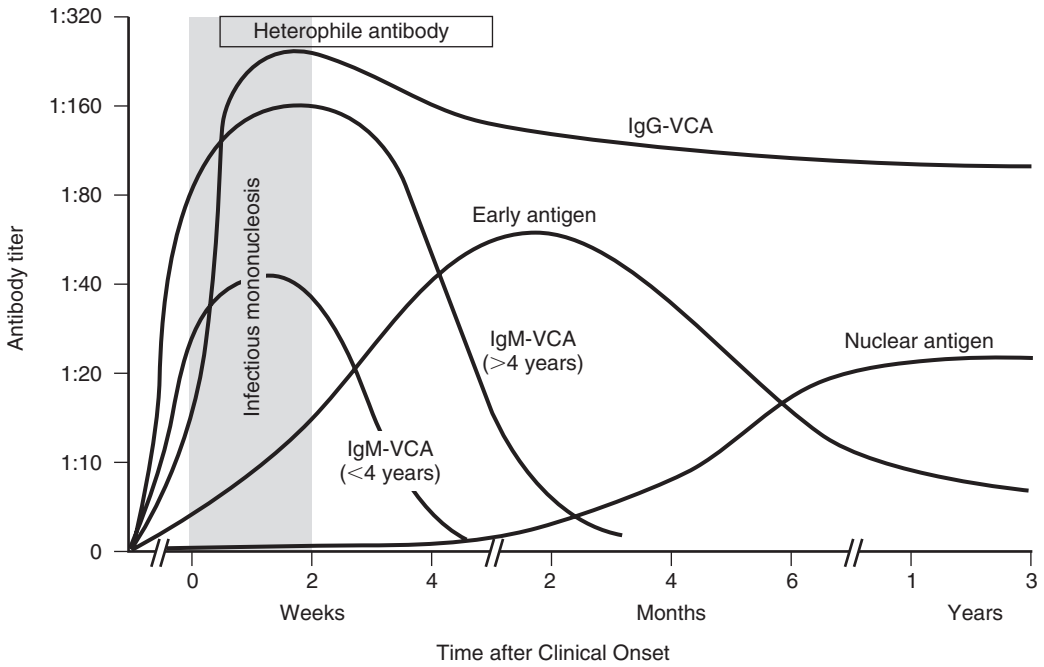

FIGURE 159-7 ■ Schematic representation of the evolution of antibodies to various Epstein-Barr virus antigens in patients with infectious mononucleosis. The titers are geometric mean values expressed as reciprocals of the serum dilution. The minimal titer tested for viral capsid antigen (VCA) and early antigen (EA) antibodies was 1:10; for Epstein-Barr nuclear antigen (EBNA), it was 1:2.5. The IgM response to capsid antigen was divided because of the significant differences noted according to age. (From Jenson HB, Ench Y, Sumaya CV. Epstein-Barr virus. In: Rose NR, de Macario EC, Folds JD, et al, editors. *Manual of clinical laboratory immunology*. 5th ed. Washington, DC: American Society for Microbiology; 1997. p. 634-43.)

in Figure 159-7. By the time clinical evaluation for IM and probably other forms of primary EBV infection is performed, an appreciable antibody response to EBV VCA has developed in most persons.[209,493] In the case of primary infections (e.g., IM), the initial serum sample often contains both IgG and IgM antibodies to VCA. Most children also have (or they will develop shortly) antibodies to the EA complex, which can be measured separately as antibodies to the restricted (R) or diffuse (D) components.[138,493] During the early phase of primary infection, most persons do not have detectable IgG antibodies to EBNA; a few have marginally detectable anti-EBNA titers. Thus, the serologic diagnosis of a recent or current primary EBV infection typically consists of a positive IgG and IgM anti-VCA response and negative anti-EBNA, with positive results in the anti-EA assay, if it is performed.

After the acute primary EBV infection (reflected in IM), IgM antibodies to VCA typically disappear within 2 to 3 months, and IgG antibodies to EA usually disappear within 6 to 12 months after infection (see Fig. 159-7).[493,495] IgG anti-VCA and anti-EBNA antibodies persist for life and are indicative of a typical, chronic virus-carrying state.[493] Some studies also have shown the persistence of anti-EA antibodies for several years after an acute EBV infection and the occasional appearance of anti-EA antibodies in healthy seropositive persons; however, the clinical or virologic importance of this finding is not clear. Heterophil antibodies may persist for months and sometimes for a year or more in persons who have recovered from IM; they remain detectable longer (usually more than a year) when the more sensitive horse erythrocyte agglutination and a quantitative method to determine the antibody response are used.

The antibody profile for an acute primary EBV infection, particularly that associated with an IM episode, is relatively clear in comparison with the variability of serologic or antibody profiles found in persons with other EBV-related disorders (Table 159-3). When a disease is not a consequence of primary infection but may be related to persistent or reactivated EBV infection (e.g., BL, NPC, some lymphomas of immunocompromised hosts, some chronic or atypical illnesses), the following serologic profile may be observed: positive IgG anti-VCA, often in high titer; usually negative IgM anti-VCA; often elevated anti-EA titer; and positive anti-EBNA assay (although sometimes at low titer and occasionally undetectable).* Of note is that males with XLP frequently have no or low levels of EBV antibodies in response to EBV infection.[449]

Some studies[342,429,440] suggest that monitoring for decreases in anti-EBNA antibodies or identification of increased immunologic mediators such as interleukin-4 and soluble CD23 and increased circulating EBV may be useful in providing early serologic signs of EBV-associated tumor development in organ and bone marrow transplant recipients. Further, testing for IgA antibody responses to EBV antigens may be helpful in establishing a diagnosis and evaluating the response to therapy for NPC.[266]

Molecular cloning of subregions of the EBV genome into high-expression plasmid vectors can generate large

amounts of pure proteins containing EBV-encoded polypeptide sequences for use in immunoblot and enzyme-linked immunosorbent assay (ELISA)–based tests.* These methods have extended the availability and use of EBV laboratory diagnosis and follow-up. There is a growing number of commercially available EBV serologic tests, particularly enzyme immunoassays.[52,214] Yet after several decades of use, immunofluorescent techniques still remain the "gold standard" in EBV-specific serologic testing because of their overall excellent specificity and sensitivity. However, they require more expensive equipment, time, effort, and experience in interpretation. ELISAs are important alternatives for serologic testing because of their ease in performance and enhanced sensitivity. However, their specificity may be inferior to that of immunofluorescent techniques.[314] It is noteworthy that there is insufficient standardization of antigen preparation, antigen and substrate selection, and cross-comparability of serologic techniques and manufacturers involved with commercially available EBV serologic tests. Therefore, interpretations should be drawn carefully, particularly with serum of young children, an age group that has been less well evaluated.[313]

Improvements in standardization as well as in specificity and sensitivity of commercially available serologic testing would benefit the laboratory diagnosis of primary EBV infections. Current EBV-specific serologic testing for nonprimary infections, particularly in immunocompromised patients, provides more limited diagnostic interpretations. The expanding capacity in the detection and quantitation of EBV viral load in body compartments and lesions (see next section) is of growing diagnostic importance in these circumstances.

Epstein-Barr Virus Nucleic Acid (DNA or RNA)

In young patients, EBV serologic testing may reveal false-positive results owing to retained maternal antibodies from the placenta, excessive blood product infusions, or asymptomatic seroconversion. In patients treated with immunosuppressants, a false-negative serologic response to EBV antigens may occur. In such situations, demonstrating EBV nucleic acid in tissue sections or in blood may be necessary for diagnostic purposes.[8] Methods include Southern blotting, in situ hybridization, and detection of EBV DNA by PCR.[49] Besides their utility as diagnostic aids, these tests also are useful for epidemiologic and pathogenetic purposes relevant to EBV infections.

Southern blot hybridization has been useful in demonstrating the association of EBV with disease.[14,49,538] Although it is not as sensitive as PCR, Southern blotting has the advantages of providing additional information about the monoclonality of EBV-associated lesions, detecting lytic EBV processes, and recognizing viral integration into the genome.[172,182,186,418]

Because of their ubiquity in EBV-infected cells (up to 10^7 copies per cell), detection of EBERs in tissues by in situ RNA hybridization has become a standard method for detecting and localizing latent EBV in tissues.[32,183,333] Probes for detection of EBERs (riboprobes) are labeled conveniently by immunoperoxidase methods. Detection of EBV DNA by in situ hybridization also can be performed,[48] although DNA detection is less sensitive because of the lower copy numbers per cell in comparison with EBERs.

Amplification of EBV DNA by PCR has emerged as an important test for establishing the diagnosis and treatment of several EBV-associated diseases. In adult patients

with AIDS and primary CNS lymphomas, detection of EBV DNA in CSF has high sensitivity and specificity in most studies.[18,77,93,333] PCR for EBV in CSF, possibly in combination with certain imaging studies,[18] may be sufficient to establish the diagnosis of CNS lymphoma and could preclude performance of brain biopsy, which can be associated with complications. On the other hand, lumbar puncture in patients with cerebral lesions also must be considered carefully because of the risk for cerebral herniation.

In stem cell and solid-organ transplant recipients, quantitative PCR for EBV DNA in peripheral blood serves as a useful tool for the diagnosis of PTLD and as a marker during follow-up.[171,309,530,559] Levels of EBV DNA in blood typically are low in healthy control subjects, high in those with PTLD or other EBV-associated diseases, and intermediate in asymptomatic organ transplant patients. A high EBV load in the blood has a clear relationship with development of PTLD,[170] and with successful management, EBV DNA concentrations typically diminish to baseline levels.[170,228,230,438] Although negative predictive values for these tests are higher than 90 percent, positive predictive values are substantially lower. Healthy subjects with IM, asymptomatic seroconverters, and transplant recipients with PTLD may have comparably high levels of EBV detected in the blood, thus making it difficult to separate out true PTLD from increases unassociated with PTLD. Detection of EBV within cellular specimens, such as whole blood or peripheral blood mononuclear cells, appears to be more reproducible and accurate than are tests measuring cell-free EBV in plasma or serum. Further studies clearly are necessary to establish quantitative laboratory standards for diagnosis and monitoring of EBV-associated PTLD. Histopathologic evaluation of a suspicious tumor site is much more informative and less controversial regarding diagnostic utility.

Quantitative PCR also may be useful for diagnosis and monitoring of other EBV-associated malignant diseases, including NPC,[304] HD,[310] and NHL.[484] Larger studies are necessary to define better the role of EBV viral load testing in these diseases. PCR testing may also be of assistance in the laboratory testing for EBV-induced disease (as IM) in young children and infants.[73,109]

Epstein-Barr Virus Proteins

Immunofluorescent techniques may be used to detect the presence of cells carrying EBV proteins in touch imprints of biopsy material or in frozen sections of cryopreserved tissue.[172,333,408,562] Most commonly, tissues are examined for VCA, EBNA-1, and LMP-1 proteins with the use of mouse monoclonal antibodies.

Virus Isolation

EBV from blood or oropharyngeal specimens (rarely, other specimens) can be isolated in tissue culture with a transformation assay.[254] For oropharyngeal specimens, the test requires incubation with fresh cord blood mononuclear cells for as long as 6 weeks. Transforming virus can be identified in peripheral blood by incubating mononuclear cells in the presence of cyclosporine (for inhibition of cytotoxic T cells, which can suppress the growth of EBV-positive B cells). An end-point dilution assay may be used to quantitate the amount of EBV within blood specimens.[436] Virus isolation tests are used primarily for research purposes and are not widely available.

Electron Microscopy

EBV virions also may be detected by electron microscopy, which has been used in patients with oral hairy leukoplakia,[244] NPC,[21] and other EBV-associated lesions. The ultrastructural features of EBV virions, however, are indistinguishable from those of other herpesviruses, and confirmatory tests usually are necessary. Electron microscopy generally is available only at larger research centers and therefore is impractical for routine diagnostic testing.

Imaging Studies

Imaging studies seldom are necessary in typical patients with IM. In one study of patients hospitalized with IM, the most common findings on chest radiography were splenomegaly (47%), hilar adenopathy (13%), and interstitial infiltrates (5%).[298] Imaging studies are used more commonly for evaluation of EBV-associated neurologic disease, especially in immunocompromised patients. Children with EBV-associated encephalitis usually have normal neuroimaging results.[106] However, some patients may display diffuse swelling or patchy low-density lesions by computed tomography, and magnetic resonance imaging may reveal increased signal on T2-weighted images as well as atrophy.[106,461] Contrast-enhanced computed tomography scans of primary cerebral lymphoma in patients with AIDS typically reveal large (2 to 6 mm) lesions occurring anywhere in the cerebrum with diffuse and homogeneous enhancement[502]; however, some overlap exists with findings observed in other diseases, such as cerebral toxoplasmosis. Thallium 201 single-photon emission computed tomography, in conjunction with magnetic resonance imaging and PCR testing of CSF for EBV DNA, may be useful in distinguishing CNS lymphomas from toxoplasmosis in adult patients with AIDS.[18]

DIFFERENTIAL DIAGNOSIS

Infectious Mononucleosis. EBV causes an estimated 80 to 95 percent of IM syndromes.[497] Numerous agents have been associated with heterophil-negative IM. CMV is responsible for most cases of heterophil-negative IM with typical clinical and hematologic findings.[228] Certain features of CMV mononucleosis may help distinguish it from EBV (e.g., less common sore throat and lymphadenopathy, less intense atypical lymphocytosis, and prominent splenomegaly), but these characteristics have considerable overlap with EBV-associated IM. Serologic testing consistent with acute CMV infection in the

absence of characteristic EBV serologic findings confirms the diagnosis. The remainder of cases may be attributable to infection with *Toxoplasma gondii*, adenoviruses, rubella virus, and hepatitis A virus. Acute HIV syndrome also may mimic IM. However, in children with non-EBV IM, the etiology frequently remains elusive. In heterophil-negative children with mononucleosis and both the clinical and hematologic characteristics of the syndrome, the most likely known agents are EBV and CMV.

Other EBV-Associated Disorders. EBV-associated HLH may be confused with IM, systemic connective tissue disorders, septicemia, and certain hematologic malignant neoplasms.[239] EBV-associated CNS lymphomas in adults with AIDS are difficult to distinguish from cerebral toxoplasmosis on the basis of clinical findings and imaging studies. Historically, a negative *T. gondii* serum antibody test response eliminates toxoplasmosis, whereas a positive test response may necessitate a trial of antitoxoplasmic therapy. Response within a week suggests toxoplasmosis, but a nonresponse indicates the need for stereotactic brain biopsy to establish a diagnosis. Identification of EBV DNA in CSF by PCR may help confirm the diagnosis of lymphoma. Because PTLDs may affect the graft, a high EBV viral load in conjunction with graft abnormalities (e.g., elevated liver enzyme values in a liver transplant recipient) may be confused with graft rejection; histologic evaluation of biopsy tissue from the graft should differentiate PTLD from acute graft rejection.

TREATMENT

Infectious Mononucleosis

Supportive Care. Support, including rest, fluids, and antipyretics, is all that is required for uncomplicated IM. Although clinical trials and case reports dating to the 1950s generally have demonstrated a beneficial effect of corticosteroids in reducing the symptoms associated with IM (e.g., fever, pharyngitis, lymphadenitis), current guidelines suggest that physicians use corticosteroids cautiously if at all.[350] This decision is based partly on the unknown long-term consequences of such therapy, including a potential deleterious effect on the immune system. Nonetheless, small series and anecdotal reports suggest that some severely symptomatic patients (e.g., those with high fever, severe pharyngitis) may benefit from short-term courses of corticosteroids.[13,35,47] Although little controversy exists about the use of corticosteroids for patients with complicated illnesses (e.g., with stridor from massively enlarged tonsils or paratracheal adenopathy, or for those with hematologic or neurologic complications; see Complications of Infectious Mononucleosis earlier), personal experience and clinical judgment largely dictate the use of corticosteroids in practice.[105,514] For example, in a report of patients with IM evaluated as outpatients and inpatients, 45 percent received systemic corticosteroids, with only a small proportion (<10%) of these patients having airway concerns.[514]

Antiviral Treatment. Numerous antiviral agents inhibit replication of EBV in vitro. Such agents include acyclovir, famciclovir, penciclovir, ganciclovir, and other nucleoside analogues.* None of these agents is capable of eliminating latent EBV present as episomes in infected cells. Five randomized, placebo-controlled trials of acyclovir (with or without corticosteroids) in adolescents and adults with IM demonstrated no beneficial effect in resolving the clinical signs and symptoms associated with illness as well as no reduced rate of complications.[11,12,387,522,523] Moreover, a meta-analysis substantiated these findings.[519] Acyclovir did significantly reduce the rate of EBV shedding in the oropharynx, albeit temporarily.[519] A study reported a decrease in the quantity of EBV DNA in oral washings and blood as well as in illness severity during treatment with valacyclovir.[528]

Epstein-Barr Virus–Associated Malignant Diseases

Providing details about treatment of EBV-associated lymphoproliferative diseases, including lymphomas, is beyond the scope of this chapter. Pediatric oncologists must be involved in the care of children with these malignant diseases. A brief overview of treatment of the principal diseases is provided.

Posttransplant Lymphoproliferative Disease

The most effective therapy for PTLD in transplant recipients is reduction (or complete elimination)[236] of immunosuppression to allow more effective control of rampant EBV infection by the cell-mediated immune system. This measure halts progression of PTLD in approximately two thirds of pediatric solid-organ transplant recipients developing polymorphic PTLD in the first year after undergoing transplantation.[171] Decisions concerning reduction of immunosuppression must be weighed against the risk of graft rejection, and careful follow-up with frequent EBV viral load measurements must be ensured. If no improvement occurs after a trial of reduced immune suppression, other therapeutic modalities must be considered singly or in combination.

Although antiviral agents (acyclovir, ganciclovir, valganciclovir) are used frequently for PTLD, largely on the basis of an anecdotal report published in 1982,[196] no clinical trials have confirmed their efficacy. Because these agents treat lytic EBV infections, yet PTLD primarily involves latent virus, the consensus has been that these agents should have minimal impact on PTLD. However, this view has been challenged by reports in experimental animals suggesting that the small proportion of lytically infected cells within these tumors may contribute to the growth of EBV-associated malignant lesions by enhancing angiogenesis and inducing paracrine B-cell growth factors.[226,227]

There is now considerable experience with the use of rituximab, a chimeric monoclonal antibody directed at CD20, against PTLD.[161] Although no randomized controlled clinical trials have been conducted to date in

*References 26, 83, 96, 164, 326, 481.

children, data from cohort studies, case reports, and a phase II trial indicate that rituximab is safe and effective.[161,179] Most adverse events are mild or moderate and usually are related to the first infusion of the antibody. Despite a profound reduction of circulating B cells in peripheral blood, hypogammaglobulinemia is an uncommon occurrence with rituximab treatment (although more likely in young children), and patients are not at higher risk for development of infectious complications. Most centers now use rituximab as a primary therapeutic agent for PTLD if reduction of immune suppression is unsuccessful.

IFN-α has induced complete remissions in some studies,[97,320] but relapses and graft rejections have occurred. Conventional NHL chemotherapy (CHOP regimen) consisting of cyclophosphamide, daunorubicin, vincristine, and prednisone may have increased toxicity and mortality associated with infection when standard doses are used,[368,481,500] thus leading to investigation of low-dose CHOP regimens consisting of cyclophosphamide and prednisone.[30,178]

Experimental therapy using EBV-specific cytotoxic T lymphocytes has been successful for PTLD in human stem cell transplant recipients,[441] but it is more complicated for solid-organ transplant recipients with PTLD. In contrast to stem cell transplant recipients, whose EBV-associated PTLD tumors are derived from the donor, tumors in solid-organ transplant recipients are invariably derived from the recipient. Therefore, EBV-specific cytotoxic T lymphocytes must be prepared by ex vivo EBV transformation of either the recipient's B cells[44,159,278] or at least partially HLA-matched banked B cells.[198] Surgery and radiation therapy generally are reserved for local complications of tumors, including compression of an airway or gastrointestinal bleeding,[171] but they have been used more widely at some institutions.[84] A multifaceted approach, such as that used by Comoli and colleagues,[84] ultimately may yield the highest response rates against the most aggressive forms of PTLD. Clinical trials of cytotoxic T lymphocytes as prophylaxis and treatment of PTLD continue to show promising results.[44,159]

B-Cell Lymphoma

Endemic (African) BLs, which are highly associated with EBV,[293] are treated primarily with cyclophosphamide-based chemotherapy.[294,569] Favorable responses were observed by Labrecque and coworkers[294] in patients with tumors expressing lytic genes. Treatment of sporadic BL also is based primarily on multiagent chemotherapy that includes cyclophosphamide.[323] Case reports have indicated positive responses to rituximab, and Children's Oncology Group protocols now include rituximab as first-line treatment of BL.[161]

B-cell lymphomas in patients with AIDS are extremely difficult to treat, primarily because of the underlying severe host immune deficiency. Early regimens using standard chemotherapeutic regimens were largely failures, with survival rates lower than those of untreated patients; most patients died of opportunistic infections, drug toxicity, and resistant tumors. Alternative therapeutic strategies have improved outcomes for this malignant disease, yet mortality rates remain substantial.[329] These strategies have included lower doses of standard drugs,[267] continuous infusion of chemotherapy,[465] hematopoietic growth factors,[300] novel immunotherapies (e.g., interleukin-2),[37] and adoptive immunotherapy[542] as well as improved management of opportunistic infections and HIV infection. In vitro data indicate the effectiveness of anti–NF-κB treatments, including bortezomib[572] and certain statin drugs,[271] and the hope is that human studies will follow. An exciting emerging area of therapy is termed lytic induction and involves treatment of EBV-positive lymphoma cells with certain agents that induce a transition from latent to lytic infection, thus rendering them susceptible to antiviral therapy (e.g., ganciclovir).[94]

AIDS-related primary CNS lymphomas are extremely difficult to treat. Historically, palliative whole brain radiation therapy in conjunction with corticosteroids was used for treatment but with disappointing survival rates of only a few months. Combined modality therapy with whole brain radiation and chemotherapy has been investigated but generally also produces poor outcomes.[268] However, most studies were conducted before wide availability of HAART. A minority of healthier patients with AIDS may respond better to combined modality regimens.[268] For patients not already receiving HAART, initiation of an appropriate regimen is recommended because case reports have described improvement.

Hodgkin Disease

Historically, children with HD were treated with high-dose radiation. However, high rates of skeletal growth inhibition and secondary malignant neoplasms were noted in survivors, so new trials using lower involved-field radiation in conjunction with multiagent chemotherapy were conducted. These trials form the basis for combination treatment regimens used currently in growing children.[234,412] Although the presence of EBV in tumor (more likely in mixed-cellularity types) currently plays no role in pretherapy staging, some studies suggest improved outcomes for patients with EBV-positive tumors.[360,366]

Nasopharyngeal Carcinoma

NPCs are sensitive to radiotherapy as well as to chemotherapy. Surgery usually is not an option because of the location of the primary tumor, although it may be necessary for persistent or recurrent lymph node disease. For early localized disease, radiotherapy generally is indicated, whereas combined modality treatment (radiation and chemotherapy) may be considered for more advanced disease.[3] Children whose treatment is failing have a high rate of distant metastases, principally to bone.[23,240]

Nonmalignant Epstein-Barr Virus–Associated Diseases

XLP. In an effort to prevent fulminant IM, intravenous immune globulin is recommended for patients with XLP who display hypogammaglobulinemia, although such

therapy is not fully effective.[153] Traditional therapy with antivirals and IFN-α has been disappointing for fulminant IM, but reported success with rituximab (in combination with corticosteroids and other agents) has provided some enthusiasm.[367] Males with XLP also can develop lymphomas, which may respond to traditional chemotherapy regimens. Presently, the only definitive cure for XLP is allogeneic hematopoietic stem cell transplantation. Fifteen such transplants were reported between 1986 and 2005, with 10 survivors.[299] Younger age appears to be associated with improved survival in this limited population. Administration of rituximab may be considered a bridge between the diagnosis of XLP and a transplantation.[299] Now that the gene defect in XLP has been identified, consideration may be given to a gene therapeutic approach.[357]

HLH. Early studies using non–etoposide-containing regimens were largely unsuccessful in significantly reducing the high mortality rate associated with HLH.[19] Chemotherapeutic regimens including etoposide (toxic to macrophages) have reduced the mortality rate significantly. Results of a standardized protocol (HLH-94) developed by the Histiocyte Society have been published.[212] Agents in this protocol included etoposide and corticosteroids for initial therapy, followed by etoposide, corticosteroids, and cyclosporine (continuation therapy), leading to bone marrow transplantation. A similar standardized protocol (HLH-2004), but including cyclosporine at initiation, currently is being evaluated.[250] Few data are available on salvage therapy for those children unresponsive to the HLH-94 protocol, but Janka[250] has summarized anecdotal successes with standard NHL or HD treatment protocols, some monoclonal antibodies (e.g., anti-CD25 and anti-CD52), and treatment with fludarabine (an antiviral agent) of one child who survived until bone marrow transplantation could be performed.

CAEBV Infection. Treatment modalities for CAEBV infection have varied widely because the rarity of this disease precludes performing proper clinical trials. Resolution of symptoms has been reported in case reports with use of antiviral drugs (e.g., acyclovir, ganciclovir),[242] etoposide,[384] immunomodulatory agents (e.g., corticosteroids, intravenous immune globulin, cytokines),[142,149,274] adoptive transfer of cytotoxic T cells,[454] or combinations thereof. For the most severe forms of disease, stem cell transplantation may be considered.[383]

HIV-Associated Diseases. Oral hairy leukoplakia generally does not require therapy because patients typically are asymptomatic and the lesions have no malignant potential. However, therapy may be required for troubling symptoms or cosmetic or psychological reasons. Small lesions may be treated topically,[361] but large lesions require systemic oral antiherpesviral agents.[390] Treatment strategies for LIP are not defined well. Supportive care, including supplemental oxygen, may be necessary. Suppression of HIV with effective antiretroviral agents also is logical to improve immune function and to minimize the potential direct effect of HIV infection. Although no controlled studies have documented the value of antiretrovirals, benefit is suggested by the declining prevalence of LIP in children during the HAART era.[167] Corticosteroids also may be of benefit.[17,352] No controlled studies have evaluated antiherpesviral drugs (e.g., acyclovir) for LIP.

PROGNOSIS

The prognosis for healthy persons with IM is extremely good, with mortality considered a rare occurrence. In a series of 30 fatal cases of IM from the 1950s, Lukes and Cox[332] found splenic rupture, Guillain-Barré syndrome, hemorrhage, and secondary infection to be the most common causes of death. In Penman's[400] later study of 20 documented deaths, predominantly of young adults, the causes of death (in order of frequency) were neurologic complications, splenic rupture, secondary infection, hepatic failure, and myocarditis. EBV-induced aplastic anemia, a rare but dreaded hematologic complication, now is thought to have a better prognosis for eventual recovery if the patient can be supported successfully through the acute stages.[31,302] It has been suggested that older patients are at higher risk for severe EBV-related IM.[508]

The prognosis for patients with EBV-associated lymphoproliferative diseases is variable and depends on the immunologic status of the patient and the type of lymphoproliferation. A registry of 161 males with XLP indicated a mortality rate of 70 percent by the age of 10 years and 100 percent by the age of 40 years.[174] HLH has a greater than 90 percent fatality rate without treatment; most deaths are caused by hemorrhage, overwhelming infection, disseminated intravascular coagulation, or multiorgan failure.[72,249] Etoposide-based treatment has improved outcomes considerably.[250] The largest case series of CAEBV infection (from Japan), which included 21 children younger than 18 years, reported a mortality rate of approximately 30 percent despite various forms of therapy.[281] Historically, PTLD that develops after solid-organ transplantation has carried a relatively high mortality rate (50% to 80%), with higher mortality rates in bone marrow transplant recipients.[131] Presently, the mortality rate is probably much lower, but more time is necessary to assess the impact of newer therapeutic modalities. The prognosis for healthy children with NHL generally is good, with 5-year relative survival rates of 80 percent.[430] However, the prognosis for patients with AIDS and NHL is poor. In adults with AIDS, median survival is 2 to 4 months for CNS lymphomas (virtually all of which are EBV associated), with only slightly longer survival noted in patients receiving HAART.[268] Childhood HD generally has a very good prognosis, with 5-year survival rates of approximately 95 percent.[430] With use of combined modality therapy, children with NPC have long-term survival rates in the range of 70 to 90 percent.[24]

PREVENTION

EBV is shed regularly in saliva, and therefore infection control policies are difficult to develop. In addition, mechanisms for EBV transmission are not well understood, and EBV outbreaks occur rarely if at all. For these reasons, no more than standard infection control precautions are recommended for patients hospitalized with EBV infections, including IM.[404] Although transfusion-associated EBV infection occurs rarely, persons with recent EBV infection of mononucleosis-like illnesses are urged to refrain from donating blood or organs.[404] Because EBV is spread

through salivary contact, individuals should avoid sharing food and drinks, especially with someone known to have had a recent EBV infection, if they wish to reduce the risk of acquiring EBV.

Vaccine

Efforts continue in the development of an EBV vaccine. Because of concern about the administration of a vaccine with unknown long-term consequences, including malignant transformation, most efforts have been focused on development of subunit EBV vaccines. A subunit vaccine containing the EBV gp350 protein has proved effective in preventing EBV infection in an experimental animal model.[120,469] A vaccinia virus–based gp350 vaccine has been evaluated in a small number of Chinese patients, eliciting good antibody responses and providing some protection from EBV infection[181]; however, these findings were not corroborated, and this vaccine was not developed further. A recombinant gp350 vaccine with adjuvant has been evaluated in Belgium, with phase I and phase II data published.[362,480] The vaccine was immunogenic, safe, and well tolerated. Although vaccine recipients were not protected from EBV infection, symptoms of IM were reduced compared with controls.[428,480] The EBV vaccine may soon enter phase III trials.[416] An effective vaccine could be considered for persons at high risk for development of EBV-associated lymphoproliferative disease and cancer, such as patients with AIDS, those with XLP, and organ or stem cell transplant recipients. Before such a vaccine is approved, further research must be conducted to address issues such as protection against exogenous superinfection from wild-type EBV strains.[532] Therapeutic vaccines, aimed primarily at latent antigens expressed in EBV-associated malignant diseases such as NPC, also are under investigation.[114,324,468] Virus-like particle–based EBV vaccine candidates are also in preclinical development.[447]

Prevention of Posttransplant Lymphoproliferative Disease

Strategies for prevention of PTLD reflect many of those used for treatment of established PTLD (see earlier section on treatment of PTLD).[357] Children at high risk for development of PTLD (e.g., EBV-seronegative children and infants younger than 12 months) typically are given prophylactic anti-CMV immune globulin and an antiviral after transplantation. A retrospective analysis of a large renal transplant database covering Europe and North America (96% adults) has suggested a beneficial effect of anti-CMV immune globulin (e.g., CytoGam) in the prevention of B-cell lymphomas.[385]

After undergoing transplantation, these children should have frequent EBV viral load testing. If EBV viral loads persist above a significant cutoff value established by the laboratory, preemptive measures should be considered. Although real-time PCR tests are sensitive in predicting development of PTLD, they are not highly specific and lack standardization. Cutoff values for "significant" concentrations of EBV DNA vary from laboratory to laboratory. Once a decision is made that preemptive therapy is warranted, reduction or elimination of immunosuppressive medications should be performed. In addition, rituximab treatment administered preemptively in patients who have significant viremia (>40,000 copies/mL in blood) may respond with resolution of viremia, without development of PTLD.[554]

Adoptive transfer of cytotoxic T lymphocytes specific for EBV, produced from donor peripheral blood mononuclear cells stimulated with EBV target antigens, is also under clinical development as an antiviral prophylactic agent as well as an antiviral treatment agent for EBV-expressing lymphoproliferative diseases in allogeneic hematopoietic stem cell transplant recipients.[44,159]

CHAPTER 160

Human Herpesviruses 6, 7, and 8

Charles Grose

As of the year 2012, there are nine human herpesviruses. Before 1986, five human herpesviruses were known. They were herpes simplex virus (HSV) type 1 (oral) and type 2 (genital), cytomegalovirus (CMV), varicella-zoster virus (VZV), and Epstein-Barr virus (EBV). The herpesviruses are important pathogens causing a variety of childhood diseases that are described in other chapters of this textbook. An inherent characteristic of herpesviruses is their ability to form a latent infection, in which the viral genome continues to reside within the host. When the virus reactivates, it often causes further symptoms and signs. Thus, herpesviruses cause a spectrum of illnesses during the lifetime of the infected human host.

During the last decades of the 20th century, four novel human herpesviruses (HHVs) were discovered. Two were originally designated HHV-6 and HHV-7, whereas the newest member of the family has been called either Kaposi sarcoma–associated herpesvirus or HHV-8. In 2012, the decision was made to separate HHV-6 into two distinct species called HHV-6A and HHV-6B. These viruses and the diseases they cause are described in this chapter. The HHV-6 strains are unique among human herpesviruses in that their genomes can occasionally integrate into the human chromosome. Because many studies of HHV-6 cited here were carried out before the formal separation into two species, the term HHV-6 often will not distinguish HHV-6A from HHV-6B species.

HUMAN HERPESVIRUSES 6A, 6B, AND 7

One unexpected consequence of the epidemic of acquired immunodeficiency syndrome (AIDS) was the discovery of a new human DNA virus. The virus was isolated first from the white blood cells of six patients with lymphoproliferative disorders, two of whom had AIDS.[27] Further electron microscopic characterization of the virus demonstrated properties of a herpesvirus, including (1) an icosahedral capsid composed of 162 capsomers covered by a lipid membrane and (2) an enveloped particle with a diameter of 200 nm (Fig. 160-1). Because the virus was isolated originally from B lymphocytes, the agent was designated human B-lymphotropic virus. However, this apparent tropism for B lymphocytes was not confirmed by other investigators, who found that the virus preferentially infected $CD4^+$ T lymphocytes and not B lymphocytes.[20,30] Thus, the initial designation of human B-lymphotropic virus was changed to HHV-6.

The DNA sequence and the deduced amino acid sequence of the HHV-6 genome have been published.[6] Calculation of the percentage of amino acid identity shared by HHV-6 proteins with those in other herpesviruses revealed that HHV-6 proteins most closely resembled those of human CMV. The strains of HHV-6 have been divided into group A and group B. The HHV-6 isolates related to prototype strain U1102 have been called group A, whereas those related to strain Z29 have been designated group B. The genomes of the group A and B viruses exhibit a 90 percent nucleotide sequence identity. In 1990, while searching for additional strains of HHV-6, Frenkel and coworkers[14] isolated a new T-lymphotropic herpesvirus that was designated HHV-7. HHV-7 is related closely at a genetic level to HHV-6 and to a lesser degree to CMV.[6] In 2012, the International Committee on Taxonomy of Viruses decided to designate HHV-6A and HHV-6B as separate species.

Most persons contract their primary HHV-6 infection before reaching the age of 5 years.[3] In the United States, primary HHV-6 infection occurred in 40 percent of children by the time they reached 12 months of age and in 77 percent by the age of 24 months.[41] In these young children, HHV-6B strains appear to be a major cause of the disease roseola (exanthem subitum). Roseola is discussed at greater length in Chapter 59. Children also may contract a primary HHV-6 infection without manifesting a rash. After acute infection, HHV-6 forms a latent infection, probably in T lymphocytes. In a small number of infants, acute HHV-7 infection appears to cause a roseola illness much like that of acute HHV-6 infection.[13a]

Diseases Caused by HHV-6 and HHV-7

Studies in Japan first delineated the nature of the illness associated with acute HHV-6 infection in young children.[37] HHV-6 was cultured from the peripheral blood leukocytes of four infants with roseola (exanthem subitum); each subject was 6 months old and had an acute febrile illness followed by a concurrent fall in temperature and onset of a rash. The blood samples were collected during the febrile stage of the disease. In a subsequent paper by the same group, two infants (6 and 7 months of age) were described who developed HHV-6 infection *without* a rash.[29] Both infants had been seen by physicians because of a 2- to 3-day history of high temperature (38.5°C to 39.5°C [101.3°F to 103.1°F]). The only abnormal clinical finding was congestion of the throat. In both cases, the temperature rapidly returned to normal around day 3 of illness, but no rash was ever observed. Cultures of peripheral blood cells from both infants were positive for HHV-6.[29] Further seroprevalence studies performed in Japan showed that most Japanese children (86%) contracted HHV-6 infection by

TABLE 160-1 **Selected Features in Roseola Associated with Infection in Children**

Clinical Findings	%
Temperature above 37.5°C (99.5°F)	98
Rash	98
Diarrhea	68
Nagayama spots	65
Cervical adenopathy	31
Edematous eyelids	30
Bulging fontanelle	26
Prodromal symptoms	14
Convulsions	8
Cough	0

Data modified from Asano Y, Grose C. Human herpesvirus type 6 infections. In: Glaser R, Jones J, editors. *Herpesvirus infections*. New York: Marcel Dekker; 1994, p. 227–4.

the time they were 24 months of age.[40] Thereafter, the increase in seropositivity among the childhood populations was small. These statistics suggest that HHV-6 infection goes unrecognized in most children.

Primary HHV-6 infection has been implicated in a few cases of severe hepatitis. The first case was that of a 21-year-old patient with cystic fibrosis who received a liver transplant.[36] The recipient lacked antibodies to HHV-6, and the organ donor was seropositive. Two weeks after undergoing transplantation, the recipient developed fever and grand mal seizures; her hepatic function deteriorated. HHV-6 was cultured from her peripheral blood cells. The apparent source of infection was the donor liver, from which HHV-6 presumably was reactivated after transplantation. She gradually recovered her hepatic function during the course of several weeks.

A fatal case of fulminant HHV-6 hepatitis has been reported in a 3-month-old boy.[4] The infant was admitted to a hospital because of fever, jaundice, convulsions, and loss of consciousness. His serum bilirubin concentration, liver transaminases, and blood ammonia level were elevated markedly. Within 7 days, he became comatose and died. As part of the diagnostic evaluation, HHV-6 was cultured from his mononuclear cells. Furthermore, HHV-6 DNA was detected in biopsy samples of liver and brain, which were obtained immediately after death. A serum sample drawn before death showed reactivity to HHV-6 antigens.

In a large retrospective review of roseola in association with acute HHV-6 infection, the signs and symptoms were tabulated.[3] The study population included 94 boys and 82 girls who ranged in age from 3 weeks to 18 months (Table 160-1). As would be predicted, the two most common clinical findings were fever and rash. The temperature often rose to 39°C (102.2°F), and fever persisted for 2 to 4 days. The rash usually appeared when the fever lessened; the rash was papular in 54 percent, macular in 40 percent, and maculopapular in the remainder of the children. The exanthem typically persisted for 3 to 4 days and was not followed by desquamation. Diarrhea was a surprisingly frequent occurrence, but it was not severe. An enanthem called Nagayama spots in Japan consisted of papules on the mucosa of the soft palate and uvula. Of the total study group, 8 percent developed febrile seizures. More severe central nervous system (CNS) complications have been documented in children not enrolled in this study. A few children with HHV-6 encephalitis have had abnormal electroencephalographic recordings. Some children with encephalitis have had permanent neurologic sequelae. In the United States in particular, acute HHV-6 infection also appears to be associated with concurrent acute otitis media.[24]

Reactivation of previous HHV-6 infection has been demonstrated in some healthy children and adults who contracted a second herpes-type infection, such as primary EBV infection (infectious mononucleosis) or primary CMV infection.[3] A similar serologic survey was performed in 10 renal transplant recipients who initially were HHV-6 seropositive.[3] After transplantation, all 10 showed greater than fourfold rises in antibody to HHV-6. Only 2 of the 10 developed a febrile illness, and both of them also had primary CMV infection. Among the human herpesviruses, HHV-6 infections are unique in that HHV-6 DNA can be integrated into a human chromosome. In a recent survey of 21 cases of integrated HHV-6 infection after transplantation, HHV-6B DNA was found more often among solid-organ transplant recipients, whereas integrated HHV-6A was more common among allogeneic hematopoietic stem cell recipients. None of the 21 transplant patients developed clinical symptoms related to the integrated HHV-6 infections.[18] Furthermore, HHV-6 does not appear to be related causally to Kawasaki disease,[22] nor does HHV-6 infection appear to alter the course of human immunodeficiency virus (HIV) infection.[28]

Whether HHV-7 causes a distinct illness has been the subject of many medical investigations since 1990. In general, HHV-7 antibody is acquired by mid-childhood, but there appears to be no corresponding sentinel illness. However, in two infants with roseola, both isolation of HHV-7 and seroconversion to HHV-7 were documented; in addition, another five children with roseola were found to have undergone seroconversion to HHV-7.[32] HHV-7 also has been isolated from one infant with an acute febrile illness.[25] Therefore, in a small number of young children, acute HHV-7 infection may be associated with fever and sometimes a roseola-like rash.

Finally, congenital infections also can occur in pregnant women already infected with HHV-6. In a survey of 5638 cord blood samples, HHV-6 DNA was detected in 57 samples (1%), but the congenital infections did not cause an identifiable disease in the newborn.[16] Of great interest, congenital HHV-6 infections appear to be caused mainly by chromosomally integrated HHV-6 DNA. Therefore, the HHV-6 genome will be present in all cell types, including tissues in the CNS of the newborn. Chromosomal integration during congenital infection appears to occur more commonly with HHV-6A than with HHV-6B species.

Neurologic Complications

In the preceding paragraphs, CNS symptoms were mentioned briefly. In a large series of clinical studies performed in Japan, seizures were a common feature of acute HHV-6 infection.[3,38] In one series of 105 young children with acute febrile convulsions, 21 had evidence of primary HHV-6 infection, as assayed by either isolation of virus from blood or seroconversion of HHV-6 antibodies. When the age of the patient was assessed, HHV-6 infection was found in 13 of 23 seizure patients younger than 1 year; thus, the seizure group with HHV-6 infection was significantly younger than the seizure group without HHV-6 infection. In addition, the frequency of clustering seizures, long-lasting seizures, partial seizures, and postictal paralysis in children having their first febrile convulsion episode was significantly higher in those with primary HHV-6 infection than in those without HHV-6 infection. One child with fatal acute necrotizing encephalitis and concurrent HHV-6 infection also has been described.[21]

In studies from Japan, assays for HHV-6 and HHV-7 DNA were performed on cerebrospinal fluid samples from 43 children with CNS symptoms.[39] All children had symptoms compatible with aseptic meningitis. HHV-6 DNA was detected in the peripheral blood cells of 15 and in the cerebrospinal fluid of 7 children; all were HHV-6 variant B. HHV-7 DNA was detected in the peripheral blood cells of 28 and in the cerebrospinal fluid of 6 patients. Thus, the clinical study demonstrated that both HHV-6 and HHV-7 can invade the CNS or, alternatively, frequently reactivate within the CNS during childhood neurologic disease. The results from Japan have been confirmed in a similar large analysis of young children with seizures in Britain and Ireland.[35] Among 156 children hospitalized with febrile seizures, 26 (17%) were associated with acute HHV-6 or HHV-7 infection. The median age for hospitalization in the HHV-6 group was 53 weeks, and the median age for the HHV-7 group was 60 weeks.

HHV-6 infection is an important cause of posttransplantation acute limbic encephalitis (PALE) after hematopoietic stem cell transplantation. Among six children who underwent cord blood transplantation for hematologic malignant disease at one hospital in Australia, six developed PALE in association with HHV-6 infection.[13a] Three patients developed confusion, general impairment of memory, and sporadic seizures. The other three had more severe symptoms, including generalized epilepsy that presented during the third week after the transplantation. The diagnosis of HHV-6 infection was made by detection of viral DNA in blood and spinal fluid. The seizures were initially controlled and the HHV-6 infection was treated. However, after another 11 to 18 months, all three patients developed generalized seizures that were much more difficult to control. All three patients experienced a severe regression in their motor and intellectual functioning.

Pathogenesis of HHV-6 and HHV-7 Infection

The pathogenesis of HHV-6 infection certainly includes a viremia while the child is asymptomatic; the total duration of the incubation period is not well defined but may be approximately 10 days. The prodrome, which signals the end of the incubation period, includes 2 to 4 days of fever, which precedes the onset of the rash.[3,26] During this period, virtually 100 percent of peripheral blood cell cultures are positive for HHV-6. By day 3 or 4, when the rash first appears, the viremia is abating. Between 5 and 7 days after the onset of the fever (or 2 to 4 days after appearance of exanthem), viremia persists in less than 20 percent of the children. Viremia is absent later in convalescence, when the antibody response is detectable. HHV-6 occasionally reactivates from latency throughout the lifetime of an infected human, but usually no apparent illness is present.[7]

The mothers of infants with HHV-6 infection have been studied to determine whether they are the source of the infectious agent.[16] Because most mothers are seropositive, the possibility exists that HHV-6 infection could reactivate in the mother, who would then transmit the infection to her child, possibly through exchange of saliva. Obviously, mothers with an integrated HHV-6 DNA infection can pass the infection to their fetus during gestation.[16] However, for mothers without an integrated infection but with HHV-6 seropositivity, HHV-6 DNA was detected in the vaginal secretions, so perinatal HHV-6 transmission remains a possibility. Older siblings are another possible source of infection within a household.[41]

In contrast with HHV-6, HHV-7 seropositivity occurs in children but often after the first 2 years of life. HHV-7 transmission has been investigated in large multigenerational Japanese families living in the same household.[31] The results indicated that HHV-7 is transmitted gradually from older generation to younger generation (Fig. 160-2). Transmission often occurs in children before the child enters a traditional primary school at the age of 6 years. Either parent or presumably an older sibling can

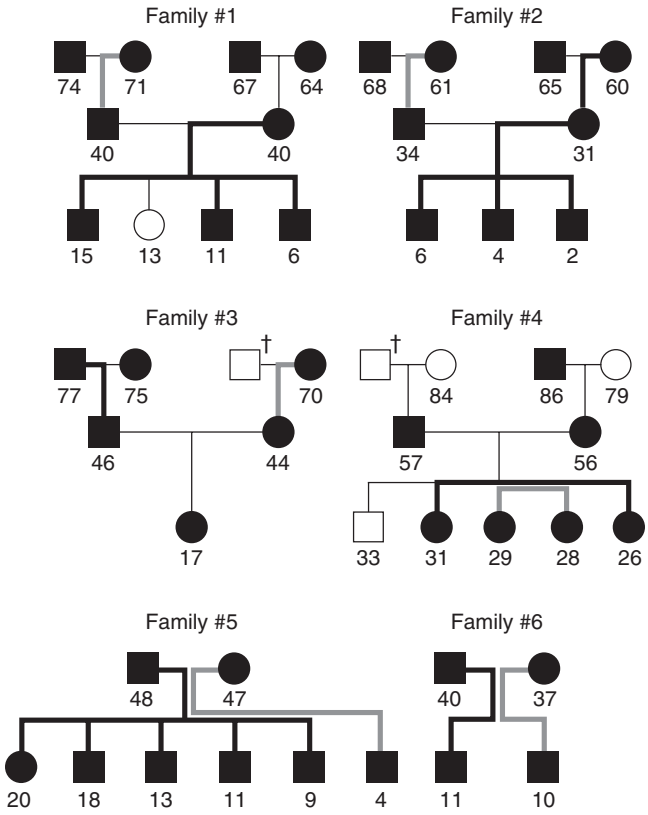

FIGURE 160-2 ■ Pedigrees of six families with HHV-7 infection. All families resided in Okayama, Japan. Males and females are indicated as boxes and circles, respectively. Persons from whom HHV-7 was isolated are shaded. A person who was already deceased is marked †. Members who have similar HHV-7 DNA restriction patterns are connected with bold lines. Numbers under the boxes and circles indicate ages. (From Takahashi Y, Yamada M, Nakamura J, et al. Transmission of human herpesvirus 7 through multigenerational families in the same household. *Pediatr Infect Dis J* 1997;**16**:975–8.)

transmit the virus. A reasonable explanation for this pattern of transmission is repeated exchange of infectious saliva among family members living in the same household during the course of many years.

Diagnosis

Infection with HHV-6 can be diagnosed by several means, including (1) measurement of antibody, (2) isolation of virus, (3) detection of viral antigen, and (4) detection of viral DNA. The first method (i.e., the traditional approach for diagnosis of virus infection) usually requires acute and convalescent serum samples for determination of a fourfold or greater rise in titer of virus-specific IgG antibody. The finding of IgM specific for HHV-6 in a single serum sample also would indicate an acute infection in a young child. The titer of IgG antibody rises during reactivation of the virus in adults, but whether IgM antibody to HHV-6 appears regularly at the same time is not known. HHV-6 antibodies usually have been measured by an indirect immunofluorescence method, although neutralization tests also have been performed.[3,4,34]

Isolation of HHV-6 was the original technique for identification of this herpesvirus.[27] The method is more difficult to perform than are those methods commonly used for most herpesviruses (e.g., HSV, CMV, VZV) but is similar to that required for isolation of another herpesvirus, EBV. HHV-6 usually is isolated in a cell substrate consisting of mononuclear cells obtained from cord blood of a newborn infant. The source of virus in the patient also is the peripheral blood mononuclear cell population.[34]

Viral genome can be detected in infected tissues by DNA hybridization techniques.[34] Viral DNA also can be detected in tissue samples by polymerase chain reaction (PCR). In one fatal case of HHV-6 infection,[4] DNA was extracted from postmortem liver and brain samples and amplified by the PCR test. On direct gel electrophoresis, HHV-6–specific DNA was detected in both the liver and the brain specimens. These studies indicate that HHV-6 infection can be diagnosed by both traditional and newer molecular techniques. Likewise, HHV-7 infection usually is diagnosed by isolation of virus or detection of viral DNA by PCR testing in samples from patients.

Treatment of HHV-6 Infection

In most instances of HHV-6 infection in healthy children, treatment with an antiviral medication is not indicated. Recovery is complete within a few days after onset of the rash, and sequelae rarely occur. However, HHV-6 disease in immunocompromised persons may be more persistent or severe (e.g., encephalitis). Several groups have analyzed the in vitro sensitivity of HHV-6 to four antiviral drugs: acyclovir, ganciclovir, phosphonoformic acid, and cidofovir.[1,3] All four compounds have been used in treatment of other herpesvirus infections. Multiplication of HHV-6 in cell culture is inhibited readily by ganciclovir at a concentration of 2 to 10 μg/mL, easily achievable levels in humans. This effect is of interest because ganciclovir inhibits human CMV to a similar degree; as mentioned earlier, CMV and HHV-6 are related closely at a genomic level. Phosphonoformic acid (foscarnet) at a concentration of 6 μg/mL also is effective against HHV-6 infection. On the other hand, HHV-6 is affected by acyclovir only at concentrations of 50 μg/mL, considerably higher levels than those required for treatment of HSV-1, HSV-2, and VZV infections and probably toxic in humans. Likewise, cidofovir is more toxic than is ganciclovir and would not be recommended for HHV-6 treatment. At present, none of these antiviral drugs has been approved specifically for treatment of HHV-6 infections. One caveat for antiviral therapy for HHV-6 infection is the consideration whether the HHV-6 infection is related to chromosomally integrated HHV-6 DNA; these patients often have high copy numbers of HHV-6 DNA in the blood. Under these circumstances, however, antiviral therapy may exert no demonstrable effect.[18]

KAPOSI SARCOMA–ASSOCIATED HERPESVIRUS (HUMAN HERPESVIRUS 8)

Yet another consequence of the HIV epidemic in the 1980s was the appearance of Kaposi sarcoma in many people with AIDS. The increase in Kaposi sarcoma was

especially puzzling because the tumor occurred more frequently in people who acquired HIV by sexual transmission rather than by infusion of infected blood products, such as factor VIII in hemophiliac patients. The question often arose whether a second infectious agent was involved in the etiology of Kaposi sarcoma. The answer to that question was provided by a report published in late 1994. The authors announced the identification of a previously unknown herpesvirus-like DNA sequence collected from patients with AIDS in New York.[9] The viral DNA was called Kaposi sarcoma–associated herpesvirus (KSHV). Other virologists prefer that the agent be called human herpesvirus 8 (HHV-8).

Diseases Caused by Kaposi Sarcoma–Associated Herpesvirus

The authors of the original KSHV report were investigating patients with Kaposi sarcoma. They discovered the herpesvirus-like DNA sequences by using a combination of genetic techniques, including amplification of DNA by PCR and subsequent representational difference analysis.[9] Thereby, they were able to identify and to characterize unique DNA sequences in Kaposi sarcoma that were absent from nonmalignant tissue from the same patient. One such sequence showed close homology to regions of the genome of *Herpesvirus saimiri*, a simian herpesvirus, and to a lesser degree to EBV, the agent that causes infectious mononucleosis. A second DNA fragment was homologous to another region in the *H. saimiri* genome. In their study, the authors located one or both of these herpesvirus-like DNA sequences in 20 of 27 different samples of Kaposi sarcoma tissue. The investigators concluded that they had discovered DNA of a previously unknown herpesvirus within Kaposi sarcoma tissues.

Their results were confirmed quickly by other groups. In one study from California, investigators detected identical viral sequences in 13 of 13 biopsy specimens of Kaposi sarcoma from patients with AIDS.[2] This study also found the same sequence in the peripheral blood cells collected from 10 of the 13 patients but not in the blood samples of 20 patients with no history of Kaposi sarcoma. A third study from France found the herpesvirus-like DNA in biopsy specimens from 5 patients with Mediterranean-type Kaposi sarcoma; all 5 patients were HIV seronegative.[11] In subsequent studies, HHV-8 DNA has been detected in most Kaposi sarcomas (classic) in HIV-seronegative individuals, often men residing in the Mediterranean area.

The authors of the original KSHV report subsequently found the herpesvirus-like DNA sequences in body cavity–based lymphomas from patients with AIDS.[8] HHV-8 DNA also has been found in the B-cell lymphoproliferative disorder known as multicentric Castleman disease.[5] Of equal importance, KSHV sequences were not found in several other lymphomas or leukemias (e.g., small-lymphocyte lymphoma, monocytoid B-cell lymphoma, follicular lymphoma, diffuse large-cell lymphoma, Burkitt lymphoma, lymphoblastic lymphoma, anaplastic large-cell lymphoma, multiple myeloma, hairy cell leukemia, acute lymphoblastic leukemia, or cutaneous T-cell lymphoma). Recently, multicentric Castleman disease has been diagnosed in an HHV-8–infected child, who may have had errors in innate immunity secondary to consanguineous parents.[19]

Transmission of HHV-8 Among Children

One of the most perplexing aspects of HHV-8 epidemiology is the mode of transmission. That the seroprevalence is high among a population of adult men who have sex with men is well known.[23] Yet, the question remains whether larger segments of the population are infected on a worldwide basis and, in particular, whether children are infected. To answer this question, several HHV-8 seroepidemiology studies were surveyed. Two studies provide partial answers to the question of childhood infection.

The first study was performed in a village in French Guiana, South America, among 1337 individuals of African origin.[24] They ranged in age from 2 to 91 years. The serologic data indicated that HHV-8 seropositivity is strongly age dependent: at the ages of 2 to 4 years, 3 of 146 were positive; at the ages of 5 to 9 years, 14 of 278 were positive; at the ages of 10 to 14 years, 31 of 232 were positive; at the ages of 15 to 19 years, 24 of 149 were positive; at the ages of 20 to 29 years, 38 of 236 were positive; at the ages of 30 to 39 years, 16 of 120 were positive; at the ages of 40 to 49 years, 19 of 70 were positive; and older than 50 years, 32 of 106 were positive. These seroprevalence data clearly show a gradual acquisition of infection during early childhood, with a stepwise increment from approximately 5 to 12 percent at the age of 10 years.

HIV infection did not play a role in the likelihood of transmission because HIV infection is not a common occurrence in this village. Instead, extensive analyses of intrafamilial relationships demonstrated a highly significant familial correlation in HHV-8 seropositivity between mother and child (especially when children were younger than 10 years) and between siblings. The correlation was highest when the siblings had an age difference of less than 5 years. Of interest, a similarity in transmission appears to exist between HHV-8 and HHV-7, when HHV-7 was studied in multigenerational Japanese households (Fig. 160-2).

A second large HHV-8 seroepidemiology analysis was performed in Israel.[10] The incidence of classic Kaposi sarcoma in Israel is among the highest in the developed world. Because of this statistic, the investigators undertook a study to ascertain the HHV-8 seroprevalence in Israel and also to investigate HHV-8 intrafamilial transmission. The study population included 1648 healthy blood donors determined to be positive for hepatitis B antigen and 2403 family members.

The seroprevalence data showed that 9 percent of children aged 2 to 14 years and 9 percent of adolescents and young adults aged 15 to 24 years were HHV-8 seropositive. Seroprevalence in older adults ranged from 12 to 18 percent. HHV-8 positivity was more likely to occur in children when at least one of the parents was positive compared with children with neither parent positive. The most important predictor of a child's HHV-8 seropositivity status was maternal seropositivity.

These two large seroepidemiologic studies demonstrate that HHV-8 is spread by nonsexual means in children in many countries around the world. In these same countries, HHV-8 seropositivity rises throughout adolescence and adulthood, regardless of HIV infection status.[33] However, in North America and western Europe, the seropositivity rate among HIV-seronegative adults is considered to be low, approximately 3 to 5 percent. The reasons for these differences between continents are not resolved. Nonetheless, the most reasonable hypothesis for transmission is exchange of saliva within family groups. Studies have proved that the virus is present in saliva, in particular in epithelial cells contained within saliva.[12] An alternative mode of infection, described next, is transmission by blood transfusion.

Hemophagocytic Lymphohistiocytosis

Hemophagocytic lymphohistiocytosis (HLH) is a rare and sometimes fatal disorder of immune regulation, often associated with mutations in the perforin gene. Even carriers of the mutated gene may require an acute infection to trigger HLH. HHV-8 is one of the triggers. HLH in association with HHV-8 infection has occurred in adults with severe HIV infection or with a recent kidney transplant.[13,19]

HLH has been diagnosed in two identical siblings from Iowa during the first 6 months of life.[15] The siblings were born prematurely and spent several months in intensive care. Both siblings had mutations in the perforin gene. Both siblings had HHV-8 infection. Because the mother of the two was negative for HHV-8 infection, one possible route of transmission was a blood transfusion given while they were in the nursery. In fact, in a large study in East Africa, blood transfusions were shown to transmit HHV-8 infection.[18] Therefore, children who have had multiple blood transfusions may be at risk for acquiring HHV-8 infection.[11]

Diagnosis and Treatment of HHV-8 Infection

Diagnosis of prior HHV-8 infection can be made by serology. Diagnosis of acute HHV-8 infection requires a scraping of cells from the mouth for testing by PCR amplification of HHV-8–specific DNA.[9,11,12] Mononuclear blood cells also may be tested by HHV-8–specific PCR. These PCR protocols are becoming more widely available.

Treatment is not necessary in most healthy hosts because the virus quickly enters latency after the primary infection. No disease has been associated with a latent infection in children, except those with defects in the perforin gene. However, acute HHV-8 infection in recent transplant recipients or HIV-seropositive children could be an indication for treatment.[13,19] Some of the same antiviral drugs described for HHV-6 treatment also inhibit HHV-8 replication (e.g., ganciclovir), but currently there are too few clinical data on which to base a standard regimen, so treatment would need to be individualized for each infected patient.

chemotherapy, organ transplantation, and irradiation. During primary infection, VZV establishes a latency in sensory nerve ganglia; zoster results when latent VZV reactivates in the ganglion. Usually, reactivation results in skin infection and produces a unilateral dermatomal eruption that may be painful or pruritic. On occasion, however, symptoms other than rash are the result of reactivation of VZV. Reactivation may also occur in the absence of symptoms.

The origin of the name "chickenpox" is uncertain, but it may have come from the French *pois chiche* (chickpea) or from the domestic fowl (in Old English, *cicen*, and in Middle High German, *kuchen*).[46] *Herpes* is the Greek word meaning "to creep," and *zoster* comes from the Greek and Latin word meaning "girdle" or "belt."

THE ORGANISM

VZV is an alpha herpesvirus. It has a DNA core surrounded by a nucleocapsid composed of 162 hexagonal capsomers that form an icosahedron with a diameter of approximately 100 nm. A tegument surrounds this structure, which in turn is surrounded by a lipid-containing envelope. Enveloped virions have a diameter of approximately 200 nm.[55] The genome of VZV has been sequenced; it contains 71 open-reading frames.[57] The linear, double-stranded DNA consists of a long unique segment, U_L, and a short unique sequence, U_S, flanked by internal and terminal repeats.[58,61,202] The genome of the Oka vaccine strain also has been sequenced; the molecular basis for attenuation of the strain is still under investigation.[4,93,139,224]

At least six genes of VZV, 4, 21, 29, 62, 63, and 66 are expressed in human sensory ganglia during latent VZV infection. VZV is synthesized by an orderly cascade of gene expression consisting of immediate-early (IE), early (E), and, finally, late (L) lytic genes that encode structural proteins. In *latent* infection there is a block in the cascade that permits synthesis of only roughly one tenth of the genes that are synthesized in productive or *lytic* infection. The genes expressed during latent infection are IE and E genes; L genes are not expressed. One hypothesis is that cellular immunity to VZV normally can control early replication of the virus so that productive or lytic infection does not occur.*

During productive or lytic infection, VZV synthesizes more than 30 polypeptides; the function of most of these polypeptides remains unknown, but some are structural and others are nonstructural and presumably have regulatory action. VZV synthesizes at least eight glycoproteins (g): gB, gC, gE, gH, gI, gK, gL and gM.[49,56,98,124] These glycoproteins correspond somewhat to those of herpes simplex virus (HSV), but, unlike HSV, VZV has no equivalent of gD, which is the major glycoprotein of HSV. The major glycoprotein of VZV is gE. The VZV glycoproteins not only provide structures for the virion but also play roles in infectivity, such as mediating adhesion and promoting entry of VZV from an infected cell into another uninfected cell. The glycoproteins also are antigenic, as is the tegument, and immune responses are directed toward these structures.

Just one antigenic type of VZV has been identified. Three major classifications of wild-type VZV were originally described, referred to as European (E), Japanese (J, for strains homologous to the Oka parental vaccine strain), and Mosaic (M, for strains displaying a combination of European and Japanese genotype-like mutations).[17,143,187,212] Worldwide, seven VZV clades have now been identified, which have differing geographic origins, that have been influenced by worldwide immigration patterns. All seven clades have been observed in the United States, although clades 1 and 3 (both E) predominate.[24]

Wild-type VZV DNA can be distinguished from that of vaccine-type (Oka) virus by restriction enzyme analysis of DNA from cultured virus and/or by polymerase chain reaction (PCR) assay and by direct sequencing, particularly of segments in open-reading frame 62, where the major mutations in Oka are present.*

VZV replicates in the nuclei of infected cells, where the DNA core and capsid are synthesized. The capsid is enveloped by a complex process in the Golgi apparatus, after which it traverses the cell in cytoplasmic vesicles.[82] In vitro, and in patients with VZV infections, the virus grows rather slowly and is highly cell associated. Its synthetic pathway entraps it in endosomic vesicles, where it is inactivated before it can be released from cells in infectious form. In vivo, however, infectious VZV is released from cells of the superficial epidermis and is highly contagious; VZV avoids the endosomal route in this particular tissue because of the loss of its receptor (the large calcium-independent mannose-6-phosphate receptor) and thereby exits cells by the secretory pathway.[43]

VZV has an extremely limited host range and infects mostly primates. Various strains of guinea pigs, including hairless ones, may be infected with VZV, but either no symptoms are produced or the illness produced is extremely mild, but specific immune responses can be demonstrated.[159] Animal models of latent VZV infection have been described in rodents, including guinea pigs.[41,155,179,223] An in vitro model of latency and reactivation of VZV in intestinal neurons from guinea pigs also has been developed.[42]

TRANSMISSION

VZV is spread by the airborne route[133] and mostly requires contact with an infected individual for transmission to occur. In varicella, VZV is transmitted mainly from the skin[43,207]; the respiratory tract cannot be excluded but is not likely to be a significant mode of spread. VZV is isolated readily from skin lesions, but isolation of the virus from the respiratory tract just before or during rash is extremely rare.[92,163,205] Spread of VZV from varicella patients before the onset of rash in closed communities has been reported, however, thus implicating respiratory

spread, although early skin lesions could have been overlooked.[25,94] VZV DNA has been detected by PCR assay in the nasopharynx of children during the preeruptive and early stages of varicella.[123,164,183] Investigations of leukemic recipients of live attenuated varicella vaccine have implicated spread of VZV from skin. No transmission to siblings from vaccinees who did not have a rash was found, but a 14 percent transmission rate occurred when siblings were exposed to a recently immunized child who had a vaccine-associated rash.[207] The chance of transmission occurring was directly proportional to the number of skin lesions present.[207] Observations in children with wild-type varicella despite their having been immunized indicated that higher transmission rates are associated with greater numbers of skin lesions.[189] Interestingly, an attack rate of more than 20 percent occurred after medical students were exposed to VZV during the autopsy of a patient with disseminated varicella; clearly, this transmission could not have occurred by the respiratory route.[166] Taken together, these observations suggest that VZV spreads mainly from skin lesions rather than from the respiratory tract. Epidemiologic studies suggest that transmission is most likely to take place in the early stages of varicella.[33,157]

Zoster is not transmissible per se, but the vesicular lesions of zoster contain infectious VZV and can transmit varicella to other individuals who have not yet had primary infection.[26,128] Zoster is perhaps 75 percent less contagious than is varicella,[177,186] and whether VZV is spread from the respiratory tract of patients with zoster is unknown. Presumably, however, the major source of contagion, as for varicella, is the skin lesions.[186]

EPIDEMIOLOGY

VZV infections occur worldwide, and both sexes are affected equally. The virus spreads less efficiently in countries with tropical climates than in those with temperate climates,[110] thereby resulting in a high rate of susceptibility in adults reared in tropical countries. In the pre-vaccine era, approximately 3.8 million cases of chickenpox, an entire birth cohort, occurred annually in the United States. At that time, 8 to 9 percent of children between the ages of 1 and 9 years contracted the illness annually.[171] These data were collected before many children attended daycare facilities; exposure to VZV in the daycare setting might have led to earlier acquisition of disease. Today there is little varicella disease in the United States owing to widespread routine vaccination. (See the later discussion of the health effects of widespread immunization in the United States.)

The link between varicella and zoster was recognized first about 100 years ago when Bokay[22] appreciated that cases of varicella often occurred after exposure to a patient with zoster. Early in the 20th century, medical investigators inoculated vesicular fluid from zoster patients into varicella-susceptible children, who then contracted chickenpox.[26,128] Weller first successfully isolated VZV in vitro, gave the virus its name, and demonstrated that the viruses isolated from patients with varicella and zoster are identical.[216] Garland proposed that zoster is the result of reactivation of latent VZV.[70] Hope-Simpson presciently recognized the importance of the immune system in preventing reactivation of VZV; he postulated that zoster results when immunity to VZV wanes with age.[109] Declining cell-mediated immunity to VZV has been identified as contributing to the development of zoster.[9,18,28,104] With the use of molecular techniques for DNA analysis, researchers have established that the DNA of the viruses causing varicella and zoster is the same, and autopsies have revealed that latent VZV is detectable in neurons of the sensory ganglia of individuals with a past history of varicella or vaccination.[53,77,121,144,147] Zoster is not acquired by contact with patients who have zoster or chickenpox.[74] Zoster develops in approximately 30 percent of the varicella-immune population during their lifetimes, resulting in an annual rate of 1 million cases.[162]

Varicella is highly contagious; clinical infection develops in 80 to 90 percent of susceptible individuals exposed in a household.[178] Secondary varicella cases in a family usually are more severe than primary cases, probably because of intensity of exposure.[170,178] Approximately 75 percent of American adults with no past history of varicella have detectable antibodies to VZV,[132] thus indicating that subclinical varicella can occur. One epidemiologic study suggests that its incidence is approximately 5 percent.[178]

Subclinical zoster also may occur, and zoster with dermatomal pain and no rash has been described (zoster sine herpete).[89] Increases in VZV immune responses and episodes of viremia shown by PCR assay in asymptomatic individuals suggest that silent reactivation occurs.[85,99,221] Asymptomatic shedding of infectious VZV does not seem to exist.

Second attacks of varicella are uncommon but may happen more frequently in persons who are immunocompromised than in immunologically normal individuals.[86,116] Immunologic boosting to VZV occurs commonly on reexposure to the virus.[8,79,86] Whether exogenous boosting is necessary for long-term maintenance of immunity to VZV is not known for certain. A recent study suggests this is unlikely; the incidence of herpes zoster was similar in isolated communities of elderly people and in those with contact with the general public.[54,67]

Adults and children older than age 2 years with zoster usually have a history of a previous attack of varicella or vaccination.[109,191] Zoster may be due to vaccine type or wild-type VZV. In vaccinated children with zoster, approximately one third of cases are caused by wild-type VZV.[39,40,68,191] Zoster is an unusual event in children, but the incidence is increased in young children who had varicella either in utero or before reaching their second birthday.[60] Chickenpox in the first year of life increases the risk for development of childhood zoster by a relative factor between roughly 3 and 21,[100] possibly because of immaturity of the immune response to VZV in young infants. Infants with the congenital varicella syndrome are at greatly increased risk, as high as 18 percent in the first few years of life, for the development of zoster.[72]

The incidence of zoster in a population begins to increase sharply at approximately 50 years of age.[109] The loss of cell-mediated immunity to VZV that occurs

naturally with normal aging contributes to the increased incidence of zoster,[18,28] and it is now known that zoster can be prevented by therapeutic immunization. In a double-blind, placebo-controlled study involving more than 38,000 healthy individuals older than 60 years, immunization with a live attenuated zoster vaccine (Oka strain) reduced the burden of illness of zoster by 61 percent.[162] Zoster vaccine in the United States contains approximately 20,000 plaque-forming units of VZV, and it is approximately 14 times as potent as monovalent varicella vaccine.[162] Recently, the efficacy and safety of this vaccine in persons between ages 50 and 59 years was demonstrated, so that this vaccine is now recommended for healthy persons older than the age of 50 years.[184] Zoster also develops with increased frequency in patients with neoplasms and organ transplants[141]; in severely immunocompromised patients with zoster, disseminated infection with viremia also may occur.[63] Spinal trauma, irradiation, and corticosteroid therapy may be additional precipitating factors. Children who are infected with human immunodeficiency virus (HIV) and have $CD4^+$ levels less than 15 percent when varicella develops are at great risk for the development of zoster; in one published series, the incidence of herpes zoster was 70 percent.[80] HIV-infected children who have received varicella vaccine, however, rarely experience zoster.[195]

On occasion, zoster may develop in healthy children or young adults who are not immunocompromised, presumably the result of a transient fall in cell-mediated immunity to VZV caused by a stimulus such as another viral infection or stress. Zoster does not develop in all immunocompromised persons; the deficiency of cell-mediated immunity to VZV is a necessary but not sufficient requirement for this illness. The distribution of lesions in chickenpox, which primarily involves the trunk and head, is reflected in a proportionately greater representation of these regions in the dermatomal lesions of zoster.[200] Zoster may recur in either the same or a different dermatome; the chance of developing recurrent zoster is similar to the chance of having a first attack for a particular age group and is reported as occurring in 2 to 5 percent of adults.[109,175]

Varicella occurs most commonly in the winter and early spring. In contrast, zoster occurs at equal rates during all seasons of the year. VZV may seed ganglia and establish neuronal latency either directly from skin lesions or by viremia.[42]

PATHOGENESIS

The incubation period of varicella ranges from 10 to 23 days (average, 14 days).[94] During the incubation period, VZV is thought to spread to regional lymph nodes, undergo multiplication, and cause a primary low-grade viremic phase after approximately 5 days that spreads the virus to the viscera, where further viral multiplication occurs. This process results in the second and greater viremic phase, which delivers the virus to the skin, where it causes the characteristic rash.[97] VZV can be isolated from blood cultures either a few days before the onset of rash or within 1 to 2 days after onset in immunocompetent children.[11] An alternative, recently proposed pathogenic mechanism is that VZV reaches keratinocytes soon after infection occurs, by virus-infected $CD4^+$ memory T cells. These memory cells, when uninfected, normally circulate through the skin. In this model, overcoming of innate immunity in skin accounts for the 2- to 3-week incubation period that follows infection.[126,127]

The skin lesions of VZV infection begin as macules and progress rapidly to papules, vesicles, pustules, and scabs. Histologic changes in the skin lesions are similar for chickenpox and zoster. The hallmarks of each disease are multinucleated giant cells and intranuclear inclusions. In varicella, they are localized primarily in the dermis and epidermis, where ballooning degeneration of cells in the deeper layers is accompanied by intercellular edema. As the edema progresses, the cornified layers and basal layers separate to form a thin-roofed vesicle. An exudate of mononuclear cells is seen in the dermis.[2,216] In zoster, in addition to skin lesions that resemble those of varicella, a mononuclear inflammatory infiltrate is present in the dorsal root ganglion of the affected dermatome. Hemorrhagic necrosis of ganglion cells and demyelination of the corresponding axon also may be present.[62,107,144]

Both humoral and cell-mediated immune responses to VZV develop within a few days after the onset of varicella. Peak antibody levels are attained 4 to 8 weeks after onset, remain high for approximately 6 months, and then decline. IgG VZV antibody titers are detectable in healthy adults for decades after recovery from varicella.[84,199,220] After active immunization against varicella, antibody titers are lower than after natural infection occurs but persist for as long as 20 years in healthy vaccinees immunized as children.[217] Serum IgG, IgA, and IgM are detectable after both varicella and zoster. Zoster occurs despite high levels of specific antibodies, but significantly higher titers develop during convalescence and are indicative of an anamnestic response to VZV in this secondary infection.[209]

Cell-mediated immune responses are thought to play the major role in host defense against the virus. Cell-mediated immunity to VZV can be demonstrated in vitro by stimulation of lymphocytes with VZV antigens,[104,225] an intradermal skin test,[132] specific lysis of histocompatible target cells by cytotoxic T cells,[6] and an enzyme-linked immunosorbent spot assay.[138] Natural killer cell and antibody-dependent cellular toxicity to VZV also has been described.[112] Immune responses of normal subjects with remote clinical evidence of varicella are characterized by occasional high activity in the absence of symptoms, thus suggesting either exposure to VZV with boosting of the immune response or subclinical reactivation of the virus. Cell-mediated immune reactions remain positive for years after a case of varicella, although this response wanes in many individuals older than 50 years.[18,28] The predominant cell in VZV vesicular lesions is the polymorphonuclear leukocyte. These leukocytes may play a role in generating interferon in vesicular lesions, which may be a factor in recovery.[201]

Exactly how immunity to varicella and zoster is mediated is unclear and also complex. Because patients with isolated agammaglobulinemia do not experience either

severe or recurrent varicella, researchers long presumed that cell-mediated immunity is more important in host defense than humoral immunity; we now recognize that T-cell cytotoxicity is crucial in recovery from VZV infection.[7] The response or responses that prevent clinical illness after reinfection with VZV are presumed to be those of cytotoxic T lymphocytes, but antibodies also may play a role. Elderly individuals with poor cell-mediated immune responses to VZV are not subject to recurrent chickenpox. In addition, specific antibodies must have some importance because passive immunization is used successfully to prevent or to modify varicella in exposed susceptible persons, perhaps by neutralization of cell-free VZV early in the infection. These issues, however, are not straightforward. Varicella may develop in young infants after exposure despite detectable transplacental antibody titers,[14] and modified cases of breakthrough varicella have developed in vaccinated leukemic children despite the presence of humoral or cell-mediated immune responses at exposure to VZV.[83,87] Still, clinical illness is far less likely to develop in individuals with detectable antibody titers or positive cell-mediated immune responses (or both) at exposure to VZV than in those without positive immune responses. Thus, some forms of cell-mediated immunity and specific antibodies each probably play roles in host defense against VZV, and there may be some redundancy in the system.

NOSOCOMIAL VARICELLA

Although it is probably less of a problem since licensure of varicella vaccine, nosocomial varicella is a potentially serious and expensive problem in hospitals, where both patients and employees may be susceptible to chickenpox.[96,102,214] Because varicella-susceptible hospital employees may serve as vectors for the spread of VZV to susceptible patients, serologic testing of employees for immunity to chickenpox if they have no past history of having had clinical varicella and offering vaccine to those who are susceptible are now standard measures in many hospitals.

The risk for horizontal transmission in maternity wards or the neonatal nursery after hospital exposure to an adult or child is surprisingly low.[72] A few episodes of nursery transmission of varicella have been reported,[66,81,101] but the low incidence of such transmission may be, at least partly, a result of the fact that many infants are in isolettes. Furthermore, most hospital employees and most mothers and their neonates have antibodies to VZV and are at low risk for the development of clinical illness. Even in low-birth-weight infants, antibodies to VZV may be detectable.[154,176]

CLINICAL MANIFESTATIONS

Varicella

Varicella is a highly contagious, usually self-limited systemic infection characterized by fever and a generalized pruritic rash lasting approximately 5 days. A prodromal phase in children is unusual, but malaise and fever for 1 to 2 days before the onset of rash is a common manifestation in adults.[46] The rash is more intense on the trunk and head than on the extremities, and it typically evolves as a series of "crops" during the course of 1 to 2 days in normal hosts. Most children with varicella have 250 to 500 superficial skin lesions, many of which are vesicular (Fig. 161-1).[178] Not uncommonly, a few lesions may develop in the mouth, conjunctiva, or other mucosal sites. Residual scarring is exceptional but can occur, and depigmented areas of skin may occur in dark-skinned patients. A self-limited increase in hepatic transaminase levels without jaundice is not an uncommon occurrence during varicella.[169] Rarely, thrombocytopenia and neutropenia may transiently occur. Severe infections are more likely to develop in adults than in children, presumably because of less robust cell-mediated immune responses to VZV in adults than in children.[75,160] Neonates who acquire varicella from their mothers in the few days before delivery also are at risk for acquisition of severe varicella because of immaturity of the cell-mediated immune response.[72]

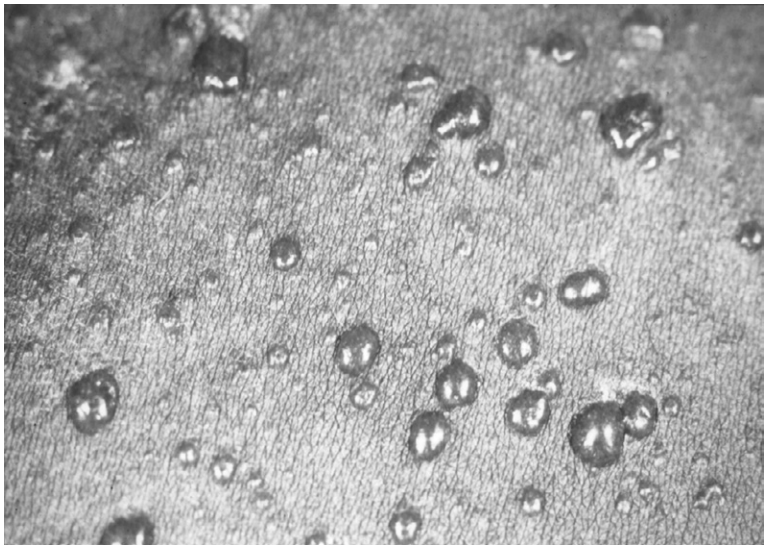

FIGURE 161-1 ■ Typical skin lesions of varicella.

Complications of Varicella

The most frequent complication of varicella in normal hosts is bacterial superinfection of the skin, lungs, or bones, most often caused by *Staphylococcus aureus* or group A β-hemolytic streptococci.[23,222] Central nervous system involvement, which may precede or follow varicella, includes transient cerebellar ataxia, severe cerebral encephalitis, aseptic meningitis, and transverse myelitis.[114,115] Encephalopathy as a sequela of Reye syndrome has become a rare complication because aspirin no longer is recommended for children with varicella. Other complications of chickenpox encountered less commonly include arthritis, glomerulonephritis, myocarditis, and purpura fulminans.[216]

Varicella may be severe and even fatal in immunocompromised patients, including those with an underlying malignant neoplasm or congenital or acquired deficits in cell-mediated immunity, such as patients who have undergone organ transplantation or have underlying HIV infection, and in children receiving high doses of corticosteroids for any reason (Fig. 161-2).[65] These patients may be susceptible to progressive varicella, with continuing fever and the development of new vesicular lesions for 2 weeks or longer. Their skin lesions characteristically are large, umbilicated, and hemorrhagic, and primary varicella pneumonia is a frequent complication. Alternatively, in some immunocompromised patients, an acute form of varicella with disseminated intravascular coagulation develops and is rapidly fatal, at times before antiviral therapy can be instituted. A 30 percent rate of dissemination with a 7 percent fatality rate was reported in leukemic children in whom chickenpox developed in the pre–antiviral drug era.[64] Severe varicella has been observed in children with underlying HIV infection, especially those classified as having acquired immunodeficiency syndrome (AIDS).[117] In most HIV-infected children, however, mild to moderate forms of varicella develop, although the illness generally is more severe than that in otherwise healthy children.[80] Varicella does not seem to be a cofactor for clinical progression of HIV infection to AIDS, but in approximately 5 percent of these children, chronic wartlike hyperkeratotic VZV lesions may develop, presumably being a chronic form of zoster in which the infection is low grade but persistent.[5]

Primary varicella pneumonia accounts for many of the fatalities ascribed to varicella, particularly in immunocompromised patients, and adults.[167] In male military recruits with varicella, radiographic evidence of pneumonia was found in 16 percent.[215] Symptoms include fever, cough, and dyspnea. Other common symptoms and signs are cyanosis, rales, hemoptysis, and chest pain. The chest radiograph typically reveals a diffuse nodular or miliary pattern that is most pronounced in the perihilar region.[204] Blood gas analyses and pulmonary function tests indicate a diffusion defect that may persist in some cases for months after recovery.[21] The availability of antiviral chemotherapy has greatly improved the outcome of this complication.

Congenital Varicella Syndrome

LaForet and Lynch, who were medical students in 1947, were the first to describe an infant with multiple congenital anomalies after contraction of maternal chickenpox.[130]

FIGURE 161-2 ■ Progressive varicella in a 9-year-old child with underlying leukemia.

The infant had hypoplasia of the right lower extremity, clubfoot, and absent right deep tendon reflexes, along with cerebral cortical atrophy, cerebellar aplasia, chorioretinitis, torticollis, insufficiency of the anal and vesical sphincters, and cicatricial cutaneous lesions on the left lower extremity. These manifestations are now recognized to be typical of this syndrome. In 1974, Srabstein and colleagues rediscovered this syndrome, which appeared to have been forgotten.[197] Their report of another case and review of the literature concluded that although the virus could not be isolated from affected infants as with congenital rubella or cytomegalovirus infection, the congenital syndrome consisted of a typical constellation of birth defects as originally described by LaForet and Lynch. This syndrome occurs after maternal VZV infection develops in the first or second trimester of pregnancy; approximately 2 percent of the offspring of pregnancies complicated by varicella are affected. Approximately 100 affected infants have been described in the literature; 95 percent occurred after maternal varicella and 5 percent after maternal zoster. In the prevaccine era, approximately 40 affected infants were thought to be born annually in the United States.[72] Today in the vaccine era, this syndrome may once more be forgotten.

Cicatricial scars of the skin, the most prominent stigmata, are reported in more than 60 percent of cases.[72] Other frequent abnormalities include chorioretinitis, microphthalmos, Horner syndrome, cataract, nystagmus, hypoplastic limbs, cortical atrophy or mental retardation (or both), and early death. Many of these children develop zoster (in which VZV can be identified) in the early months of life. There is a high correlation between limb abnormalities and a poor outcome in these infants. The Oka strain is not known to cause the congenital syndrome.[72]

Zoster

Zoster usually begins as a localized unilateral vesicular skin eruption involving one to three dermatomal segments (Fig. 161-3). The skin lesions resemble those of varicella but tend more toward confluence and are likely to be painful or pruritic, especially in adults. Zoster generally is a milder disease in children than in adults. Zoster may follow natural varicella or vaccination; however, the incidence of zoster is clearly lower after vaccination than after varicella disease, even in immunocompromised vaccinees.[103,104,206] Zoster is a considerable cause of morbidity, but mortality is unusual or rare.[148] Visceral zoster, involving the gastrointestinal tract, may produce severe abdominal symptomatology, at times in the absence of rash.[41,72]

Complications of Zoster

Two kinds of pain are associated with herpes zoster: (1) acute pain that is related to reactivation of VZV in sensory

FIGURE 161-3 ■ Zoster in an otherwise healthy 10-year-old boy.

neurons and (2) pain that develops after the acute phase of the illness, often in the area of healed rash. Between 25 and 50 percent of persons older than 50 years in whom zoster develops may experience late protracted pain, or postherpetic neuralgia, after the rash has healed. Postherpetic neuralgia also occurs frequently in immunocompromised patients. Pain may persist for months to years and is described as aching, jabbing, or boring. The cause of postherpetic neuralgia is unknown but may be related to healing of injured nerves. Otherwise healthy children rarely experience postherpetic neuralgia; both the incidence and duration are related directly to increasing age.[90,91] Zoster may be particularly severe and common after bone marrow transplantation; in the first year after undergoing transplantation, 20 to 70 percent of recipients develop zoster.[71]

DIAGNOSIS

Clinical Diagnosis of Varicella and Zoster

It usually is not difficult to establish a clinical diagnosis of VZV infection because the vesicular rash is so characteristic. In questionable cases of varicella, epidemiologic information, such as a history of recent exposure to varicella or zoster and subsequent transmission of varicella to another person, may be useful. The differential diagnosis of varicella includes generalized HSV infection, enterovirus infections, rickettsialpox, impetigo, allergic reactions, including Stevens-Johnson syndrome and poison ivy, and insect bites.

In one study of zoster, 13 percent of clinically diagnosed cases were proved by culture to be caused by HSV infection.[118] The unilateral rash of zoster most frequently appears on the trunk or face. The trigeminal nerve, most commonly the ophthalmic branch, is an especially significant site because the eye may be involved.

Laboratory Diagnosis

Laboratory diagnosis of VZV infection is facilitated by the presence of VZV in superficial skin lesions, where it is easily accessible for testing. The diagnosis is made best by the demonstration of specific viral antigens or VZV DNA in skin vesicles or scrapings. VZV antigens are demonstrable by immunofluorescence with a commercial monoclonal antibody to VZV that is conjugated to fluorescein.[73] Immunofluorescence testing is highly sensitive and can be completed within approximately an hour. PCR assay is used to demonstrate VZV in skin lesions and also in saliva and cerebrospinal fluid (CSF) when there is central nervous system involvement with VZV. PCR is more sensitive than immunofluorescence and is becoming the preferred method for diagnosis of VZV.[73,210] PCR also may be used to distinguish between vaccine (Oka strain) and wild-type VZV infections[73,174]

The diagnosis also may be made by isolation of virus from skin lesions very early in the course of illness. Within several days after the onset, vesicular fluid no longer is likely to be infectious, although viable VZV may be present in zoster lesions for a longer period, especially in immunocompromised patients. VZV cannot be isolated from skin lesions that have become pustular or dry. Isolation of VZV is a slow method because approximately 48 hours is required before the first signs of a viral cytopathic effect are seen. It is also less sensitive than is immunofluorescence or PCR. VZV rarely is isolated from respiratory secretions or from infected CSF during VZV meningitis.[92] Demonstration of VZV DNA, antigens, or isolation of virus from samples obtained from skin, other sites, or autopsy tissue is diagnostic of a current infection with VZV because, unlike other herpesviruses, no known carrier state or shedding of VZV by asymptomatic individuals exists.[73] VZV infections can also be diagnosed by demonstration of viral DNA in saliva.[136,152,153]

Numerous serologic tests, including the fluorescent antibody to membrane antigen (FAMA) method and enzyme-linked immunosorbent assay (ELISA), are useful for measuring antibodies to VZV.[73] Antibody to VZV develops within a few days after the onset of varicella, persists for many years, and is present before the onset of zoster. VZV infections may be documented by a fourfold or greater rise in VZV antibody titer in acute and convalescent serum specimens. Specific IgM in one serum specimen suggests recent VZV infection. Persistence of VZV antibody beyond 8 months of age is highly suggestive of intrauterine varicella.[81] Immunity to varicella is present if a positive FAMA titer to VZV is demonstrated on a single serum sample after varicella or immunization.[156] Serologic methods, however, particularly commercial ELISAs, may fail to identify individuals who have had natural infection or have been immunized.[73,199]

The value of serologic procedures for the diagnosis of zoster is limited. Heterologous increases in antibody titer against VZV in patients with HSV infection who previously had varicella may occur and have been ascribed to antigens common to the two viruses.[73] Laboratory diagnosis of zoster is best accomplished by PCR assay on skin lesions or in saliva.

TREATMENT

Traditionally, nonspecific measures, such as frequent bathing to discourage bacterial skin infection, antihistamines given orally, calamine lotion applied locally, oatmeal baths to decrease itching, and cutting fingernails short to discourage scratching, have been used to treat varicella. Fever is controlled best with acetaminophen rather than aspirin, which may predispose to Reye syndrome.[105] The issue of whether treatment with ibuprofen is associated with group A streptococcal superinfection in varicella has not been resolved, and, therefore, avoidance of its use for symptomatic treatment of varicella seems to be the best approach.[29,45,135,227]

Useful specific antiviral therapy for VZV became available in the mid 1980s with the introduction of the nucleoside analog acyclovir, an inhibitor of DNA polymerase and a DNA chain terminator. The antiviral effect of acyclovir depends on its being phosphorylated in the

body by virus-induced thymidine kinases, which accounts for its relative lack of toxicity.[219] Antiviral therapy for varicella and zoster is similar.

Patients with severe or potentially severe VZV infections should be treated with intravenous acyclovir 30 mg/kg/day for adults and adolescents and 1500 mg/m^2/day for children, both given in three divided doses. Orally administered acyclovir is less reliable for immunocompromised patients because only approximately 20 percent of this formulation is absorbed from the gastrointestinal tract, and no data on its efficacy in high-risk patients have been published. Because acyclovir is excreted by the kidneys, patients with a creatinine clearance of less than 50 mL/min/1.73 m^2 should receive one half to one third of this dosage. Intravenous acyclovir is infused for at least 1 hour, with maintenance fluids given both before and during the infusion. Providing adequate hydration is important to prevent renal damage from precipitation of the drug in the renal tubules. Other adverse effects of acyclovir include phlebitis, rash, nausea, and neurologic manifestations such as headache and tremor. In general, however, acyclovir is extremely well tolerated.[219]

Early intravenous therapy should be instituted for patients at high risk for development of severe VZV infection, such as leukemic children and those who have undergone organ or bone marrow transplantation, to prevent the dissemination of VZV.[192,218] Not only may this therapy be potentially lifesaving in immunocompromised patients, but it also prevents considerable morbidity from VZV infection. Children thought to be somewhat less immunocompromised, such as those with HIV infection but without AIDS, may be given a treatment trial with oral acyclovir under close medical supervision. For such patients who are not doing well, intravenous therapy should be administered. In zoster patients, the use of intravenous acyclovir is associated with more rapid healing of skin lesions and resolution of acute pain than if no specific treatment is given.[219]

Considerable controversy has ensued about the role of orally administered acyclovir for the treatment of varicella and zoster in otherwise healthy children because most of these infections are self-limited. Customarily, however, adults, who are at greater risk for development of severe infection, are treated. Oral dosages used are 80 mg/kg/day (in four divided doses) for children and 4 g/day (in five divided doses) for adults. Double-blind, placebo-controlled studies in healthy children given oral acyclovir at 80 mg/kg/day for 5 days or placebo beginning within 24 hours of the onset of varicella rash have revealed that the number of chickenpox skin lesions is reduced significantly by acyclovir. A modest benefit was derived from acyclovir; children who received it had fever for approximately 1 day less, but they did not return to school any more rapidly, nor did they have fewer complications of chickenpox.[16,59]

Some evidence indicates that early administration of oral acyclovir may decrease the acute pain associated with zoster.[111] However, the need to administer specific therapy for zoster in otherwise healthy children for whom pain is not a particular problem rarely occurs. Usually however, children with herpes zoster are treated in order to speed recovery.

The newer drug, penciclovir, has an action similar to that of acyclovir.[108] It is administered as famciclovir, a prodrug that when given orally is converted rapidly to penciclovir in the body. A major advantage of famciclovir is that it is administered only three times a day (1500 mg/day for an adult), whereas acyclovir is given four or five times daily. Penciclovir has an antiviral action similar to that of acyclovir. One study suggests that famciclovir given to elderly patients with zoster early in the course of infection decreases the duration of postherpetic neuralgia, although not its incidence.[208] No data regarding whether varicella may be treated successfully with famciclovir have been published, nor have any data on the use of famciclovir in immunocompromised patients or in children.

The prodrug of acyclovir, valacyclovir, also is given orally, reaches blood levels that are approximately three to four times higher than those following oral acyclovir, and has been shown in one study to be superior to acyclovir for treatment of zoster.[19] Valacyclovir may be used in children older than age 2 with chickenpox. The dose of valacyclovir is 20 mg/kg per dose TID for 5 days, not to exceed 1 g per dose 3 times daily.

Of concern about the potential widespread use of acyclovir is that drug resistance may develop. At present, resistance is less a problem with VZV than with HSV, but VZV resistant to acyclovir has been reported in a few patients with underlying AIDS.[113] Two vaccinated children with neuroblastoma who developed zoster caused by the Oka strain that became resistant to acyclovir after prolonged treatment have been described.[27,137] Foscarnet was licensed by the Food and Drug Administration for the treatment of VZV infections that are resistant to acyclovir and famciclovir. Foscarnet inhibits the synthesis of VZV DNA polymerase.[180,181,194] Intravenous foscarnet is given at a dosage of 180 mg/kg/day in two divided doses, adjusted according to renal function. The main toxicity of foscarnet is renal damage and electrolyte imbalance.[71]

PROGNOSIS

The prognosis of varicella and zoster is excellent in children without underlying health problems. The outlook for immunocompromised patients receiving antiviral chemotherapy also is good, especially if treatment is begun at an early stage of the illness. In general, zoster carries a better prognosis than varicella does, possibly because it is a secondary infection. If the disease is diagnosed promptly, complications such as bacterial superinfections usually can be treated successfully with antimicrobial agents. In the pre-vaccine era, despite the availability of antiviral therapy and passive immunization, the Centers for Disease Control and Prevention (CDC) has estimated that approximately 100 deaths from varicella occurred annually in the United States, mostly in children with no previous health problems. An epidemiologic study of more than 250,000 health maintenance organization records indicated that the rates of varicella in adolescents and young adults and the complication and

hospitalization rates had increased between 1992 and 1995 by a factor of approximately 5.[44]

The widespread use of varicella vaccine in the United States decreased the morbidity and mortality rates from chickenpox substantially. By 2000, in the three sentinel communities in the United States, vaccine coverage among children 19 to 35 months was more than 80 percent, and reported varicella cases had declined roughly from 70 to 80 percent, compared with the pre-vaccine era. Hospitalizations for varicella also declined by approximately 80 percent. The greatest declines occurred in young children.[161] Deaths from varicella have become rare.[150] At present, more than 90 percent of children in the United States are routinely vaccinated against varicella.[35]

PREVENTION

VZV is such an infectious agent that general measures are not useful for prevention of varicella in susceptible individuals. Some protection, however, can be achieved by isolation of hospitalized patients. Hospitalized patients with active VZV infection should be admitted to a private room, preferably with negative-pressure ventilation, and hospital personnel and visitors should wash their hands before and after entering the room and wear masks, gowns, and gloves while in it. The CDC now recommends postexposure vaccination for healthy varicella-susceptible exposed individuals.[31]

Passive Immunization Against Varicella

Varicella-susceptible children at high risk for development of severe chickenpox should be passively immunized if they are closely exposed to VZV. Passive immunization may be lifesaving; it may modify varicella or prevent it.

Passive immunization is indicated for varicella-susceptible individuals who have been closely exposed to varicella or zoster and are at high risk for development of severe chickenpox. This population includes immunocompromised children and adults, pregnant women, neonates whose mothers have active varicella at the time of delivery, and premature infants of less than 28 weeks' gestation or who weighed less than 1000 g at birth. Children at high risk should be considered to be susceptible to varicella if they have no history of having had chickenpox. False-positive antibody test results may occur in immunocompromised individuals, and, therefore, susceptible children may be identified serologically as immune; hence, a history of illness is a preferred indication of these patients' immune status. Passive immunization usually is reserved for VZV-exposed adults only if they have been proved serologically to be susceptible to chickenpox, because most adults with a negative history of varicella raised in the continental United States are immune.

Patients with HIV infection, especially those with AIDS, have some increased risk for development of severe varicella, and their management should be similar to that of immunocompromised children with regard to passive immunization. Even children who are receiving intravenous globulin for treatment of HIV infection should receive passive immunization if they have no past history of varicella and close exposure has occurred.

Infants whose mothers have an onset of chickenpox 5 days or less before delivery or within 48 hours after delivery should be given passive immunization as soon as possible after birth.[72] The transplacental route of infection and the immaturity of the immune system probably account for the severity of varicella in these infants.[72] Attack rates for varicella as high as 50 percent in infants exposed to mothers who have varicella have been reported, despite their having passive immunization.[72,173] Passively immunized infants should be observed closely, but usually they can be managed as outpatients. Intravenous acyclovir should be reserved for the rare, passively immunized infant with varicella in whom an extensive rash (more than 200 vesicles) or possible pneumonia develops.[15]

Passive immunization need not be given to full-term infants who are exposed to VZV after they are 48 hours old. Passive immunization is optional for neonates (<1 week old) if their siblings at home have active varicella. Infants exposed to VZV after birth almost always have mild varicella. Although the reported mortality rate from varicella in children younger than 1 year is four times that in older children, both rates are exceedingly low—8 per 100,000 cases and 2 per 100,000 cases, respectively.[172] The mortality rate for adults and for leukemic children receiving chemotherapy, in contrast, is 20 and 1000 times higher, respectively.[171] Passive immunization is not useful to treat or to prevent zoster. Whether it is useful for pregnant varicella-susceptible women who have been exposed to VZV to protect the fetus from developing the congenital varicella syndrome is a good possibility.[48]

Until recently, varicella-zoster immune globulin (VZIG), distributed by the Massachusetts Public Health Biological Laboratory and the American Red Cross, was used for passive immunization. Because of limited requests for VZIG since licensure of varicella vaccine in the United States, however, VZIG no longer is being produced. Another product, varicella immune globulin (human), manufactured in Canada, is now available under an investigational new drug application expanded-access protocol.[34] VariZIG can be obtained in the United States,* but central institutional review board approval is required, and local institutional review board approval also may be necessary. An alternative to VariZIG is intravenous immune globulin 400 mg/kg.

Although passive immunization has been shown to be effective when it is given within 4 days and perhaps as long as 5 days, it should be administered as soon as possible after an exposure to VZV.[3,34] In 2012, the CDC has recommended passive immunization for as long as 10 days after close exposure to VZV (based on limited data) with the possibility that it will have a salutary effect.[37] The dose is 1 vial or 125 units for every 10 kg of body weight, with a maximal dosage of 5 vials or 625 units, given intramuscularly. VariZIG should be readministered

*The sole distributor of VariZIG is FFF Enterprises in Temecula, California (800-843-7477).

to high-risk susceptible individuals who are closely reexposed 3 weeks after a first dose.[3]

Active Immunization Against Varicella

A live attenuated varicella vaccine, the Oka strain, was developed in Japan more than 35 years ago.[148] It was licensed in the United States in 1995 for universal immunization of healthy children and adults who are susceptible to varicella[30,35] and has proved to be extremely safe and well tolerated.[20,35,39,68,191] Varicella vaccine is labile. The lyophilized vaccine must be stored frozen at an average temperature of 5° F or colder. The freezer must have its own door; frost-free freezers are acceptable. Prior to use, the vaccine must be diluted with its supplied diluent and administered subcutaneously to the patient within 30 minutes to preserve its potency.[35]

Originally a monovalent formulation of varicella vaccine was licensed in the United States. Currently two licensed varicella vaccine formulations are available in the United States, both produced by Merck. Monovalent varicella vaccine, which contains 1,350 plaque-forming units (PFU) at expiry, is recommended for healthy varicella-susceptible persons older than the age of 12 months. A combination vaccine, MMRV, which was licensed in 2005, contains a larger amount of VZV than Varivax, approximately 10,000 PFU at expiry. MMRV is recommended for healthy children between 1 and 12 years of age. Varicella vaccines worldwide are the Oka strain and appear to be similar to the vaccine used in the United States.

Safety

The most frequent adverse reaction to vaccination is a mild rash that develops several weeks later in approximately 5 percent of healthy children, particularly after the first dose.[84,88,191,217] These rashes can be serious in immunocompromised children who are vaccinated inadvertently[76,78,191] but usually respond to antiviral therapy. When vaccinees develop rash from the Oka strain, the potential for transmission of the vaccine virus exists, but transmission is extremely rare from healthy individuals, with fewer than 10 reported instances from healthy vaccinated individuals after more than 15 years of routine immunization of as many as 60 million American children.[35,68,95,191] In contrast, the rate of transmission of the Oka strain was 14 percent after household exposure from vaccinees with underlying leukemia who had a rash and exposed their susceptible healthy siblings.[207]

It was observed that the incidence of febrile seizures was double that in children from 1 to 2 years of age in the 5 to 12 days after MMRV compared with monovalent varicella vaccine (one extra febrile seizure for every 2500 vaccinees).[125] After careful consideration the CDC recommended that for the first dose of measles, mumps, rubella, and varicella at age 12 to 47 months, either MMR vaccine and monovalent varicella vaccine or MMRV may be used. Providers are advised to discuss the risks and benefits of each of the two choices with the infant's parent or caregiver, particularly if it is anticipated to give MMRV; the CDC favors giving MMR and varicella vaccines in separate sites. For the second doses, at any age, and if the first dose is given at age 4 years or older, MMRV is preferred.[36]

Few serious neurologic events have been causally demonstrated to be connected to varicella vaccine. There have been nine reports of herpes zoster due to the Oka strain with accompanying meningitis (VZV DNA found in CSF by PCR assay) in a group of healthy and immunocompromised patients; all recovered with antiviral therapy.[165] It is well known that meningitis may also accompany herpes zoster caused by wild-type VZV,[38,89,168,196,198] so it is unclear whether these nine patients should be classified as having a vaccine-associated adverse event or not. Because there is no known denominator, the incidence of these complications after is not known. Transient cerebellar ataxia has been reported after vaccination, but its connection to VZV has not been proven.[68,191]

Effectiveness

Live attenuated varicella vaccine is highly effective in healthy children and adults, but not all vaccinees are completely protected. Ten to 20 percent of children given one dose may develop a modified breakthrough illness after intimate exposure to VZV. Varicella vaccine has, however, been 97 percent effective in preventing severe varicella.[210,211] The vaccine is also highly effective in adults; after two doses, more than 75 percent are completely protected from varicella after household exposure to the virus.[1,84,182] Severe wild-type varicella in vaccinated adults is very rare.

Originally, it was observed that approximately 85 percent of healthy children are protected after only one dose of vaccine,[129,210,211,217] and there was little concern about breakthrough varicella because it had been found to be almost always a modified illness. There was no significant waning of immunity in a case-control study with laboratory verification of varicella.[211] Loss of VZV antibodies, moreover, occurs rarely in healthy vaccinated children, some of whom have been monitored for as long as 20 years after immunization.*

Beginning in approximately 2000, however, breakthrough varicella became a growing concern in the United States. The incidence of varicella in sentinel geographic areas where active surveillance was being performed revealed that although the incidence of disease fell after 1995, it leveled off at a low rate in about 2000.[188,189] The number of reports of outbreaks of varicella among vaccinated children was, moreover, increasing; some of these studies indicated vaccine effectiveness as low as 44 and 56 percent, although most showed 80 to 85 percent effectiveness.[69,134] Also recognized was that children with breakthrough infections could spread wild-type VZV to contacts almost as efficiently as unvaccinated children with varicella.[189] Attempts at outbreak control with second doses of varicella vaccine proved to be expensive and complicated.[149] Finally, one study suggested that the seroconversion rate could be as low as 76 percent, indicating an unexpectedly high rate of primary

*References 10, 12, 47, 129, 193, 213, 226.

vaccine failure after one dose of vaccine.[156] The fear was that without a second routine dose, a gradual accumulation of susceptible young adults would develop as a result of primary vaccine failure and would be at risk to develop severe chickenpox.

In the light of all these problems, a second dose of varicella vaccine was recommended for all children, not just those older than 12 years, by the CDC in June 2006. Early studies exploring immune responses to two doses had indicated the safety of a second dose and a marked boost in immunity and the seroconversion rate afterward. An interval of 4 to 6 years between the first and second doses was recommended in 2007, but there was flexibility in that the second dose could be administered at any time 1 month after the first dose.[35] Catch-up immunization was also recommended for children who received only one dose of varicella vaccine.[35] With the institution of two routine doses, protection achieved 98 percent in a case-control study,[190] and the incidence of varicella was reported to have decreased significantly in Connecticut.[119]

Because the risk from wild-type VZV is greater than is the risk from vaccine-type VZV, immunization is recommended for health care workers and persons whose varicella-susceptible family members are immunocompromised or pregnant.[35] Varicella vaccine is recommended only for healthy persons. Vaccinees in whom an extensive VZV rash develops within 2 to 3 weeks after immunization are likely to have wild-type infection.[191] In such situations, PCR and restriction fragment length polymorphism analysis can be used to differentiate between wild-type and vaccine-type VZV. Passive immunization could be considered for immunocompromised individuals inadvertently exposed to a vaccinee with rash resembling chickenpox that might be caused by wild-type VZV.

Most states now require varicella vaccination for children to attend daycare or school. In geographic areas where vaccine use in children younger than 3 years is 70 percent or more, the incidence of varicella has decreased sharply, not only in the vaccinated group but also in all age groups, a process indicative of herd immunity.[188,195] As has been mentioned, the incidence of zoster appears to be less of a problem after immunization than after natural infection in vaccinated immunocompromised individuals and in healthy vaccinees.

HIV-infected children may be immunized with monovalent varicella vaccine if they are free of symptoms and have 15 percent or more CD4 T lymphocytes (for children > 8 years old, a CD4 T lymphocyte level of ≥200 cells/μL is used). For these children, varicella vaccine has been shown to be safe, immunogenic, and effective.[35,195]

Drug Prophylaxis

Prophylaxis of varicella in exposed persons may be achieved by the administration of acyclovir.[13,110,140,203] This approach is not recommended often, however, because the optimal dosage and timing of administration have not been studied in large groups of children, nor is it known whether long-term maintenance of immunity exists in all children. In the United States, prevention of varicella by vaccination is a preferable approach. Long-term acyclovir therapy may be used to prevent the development of zoster in patients who have undergone bone marrow transplantation; however, its value is questionable because zoster commonly develops after administration of acyclovir is stopped.[32]

CHAPTER 162

SMALLPOX (VARIOLA VIRUS)

James D. Cherry

Smallpox was a dreaded febrile exanthematous disease caused by the orthopoxvirus variola virus.* After an extensive decade-long World Health Organization (WHO) program to eradicate smallpox, the world was certified free of smallpox in 1979.[14,78] Increased concern relating to biologic terrorism occurred during the 1990s, and the events of September 11, 2001 and immediately thereafter brought home the potential reality of this threat for the present and future.†

HISTORY*

Evidence suggests that endemic smallpox was occurring before 1500 BCE. Three mummies dating from the 18th to the 20th dynasties in Egypt had pustular lesions all over their bodies.[30] Reliable written accounts of smallpox first appeared during the 4th century. Smallpox was differentiated from measles in 340 CE by Ko Hung in China. At that time in China, smallpox was an established

endemic disease that had come from the west 300 years earlier. During the period from 340 to 1000 CE, the disease was described in Egypt, India, Korea, Japan, southern Europe, and North Africa. A major contributor to the spread of smallpox was the great Islamic expansion across North Africa and into Spain in the 7th and 8th centuries.

By the year 1000 CE, smallpox probably was endemic in populated areas of Europe, Asia, and the African Mediterranean countries. Smallpox was established further in northern Europe by the population movements related to the Crusades. By the 16th century, smallpox was a serious disease in Europe, as indicated by death statistics in Geneva, London, and Sweden. In London during the 17th century, approximately 10 percent of the yearly deaths were attributed to smallpox.

The disease was introduced into the American colonies in 1507 and into Mexico soon thereafter. Epidemics of smallpox posed serious problems for the colonists, as well as for the Native Americans. These epidemics also may have been important in certain stages of the American Revolution.[4,32] Smallpox persisted in the United States and Mexico until the 1940s and 1950s, respectively, despite concerted efforts to eliminate the problem.

Soon after this disease was recognized, the Chinese are reported to have made efforts to prevent it. The technique used presumably was variolation, the intentional intranasal or intracutaneous inoculation of susceptible persons with vesicular fluid or crusts from patients with smallpox. This technique apparently originated in China and subsequently was used in many countries, including the United States. As recently as 1968 and 1969, isolated instances of the use of variolation were noted in remote areas of Africa and Asia.[32,47]

After making his observations in 1796 on the immunity against smallpox that was conferred by inoculation with material obtained from cowpox lesions, Jenner extended his research to include intentional and deliberate exposure of some of those persons immunized with cowpox. This strategy provided convincing evidence of solid protection against smallpox.[50] Encouraged by the results, Jenner predicted in 1801 the ultimate eradication of smallpox, a remarkable prediction indeed.[32,42]

The Intensified Smallpox Eradication Program of the WHO, established in 1967, initiated remarkable progress toward total global eradication of this disease.[41,45] Several factors responsible for this rapid progress included emphasis on surveillance of disease, with containment rather than routine vaccination; improved vaccines and vaccination technology; and sound administrative and fiscal support.[32,33,44,45,54] Of the more than 30 countries in 1967 in which smallpox was endemic, the disease persisted in only 5 in 1975 and in 2 in 1977. The world's last case of endemic smallpox occurred on October 31, 1977, in Merca, Somalia.[26] A year later, in 1978, a photographer working at the University of Birmingham in England was infected with a laboratory strain of smallpox virus and died.[74]

After the worldwide eradication of smallpox was achieved, the World Health Assembly (WHA) in 1980 recommended that all countries cease vaccination.[78] Subsequently, a WHO expert committee recommended that all laboratories throughout the world destroy their stocks of variola virus or transfer them into either of two WHO reference laboratories.[46] The laboratories were the Russian State Research Center on Virology and Biotechnology, Koltsovo, Novosibirsk Region, and the Centers for Disease Control and Prevention (CDC) in Atlanta, Georgia.[6] Reportedly, all countries complied with this recommendation.

The WHO committee at a later date recommended that all variola virus stocks be destroyed by 1999, and the WHA concurred with this recommendation.[8] In 1998, a committee of the Institute of Medicine reviewed the possible importance of retaining variola virus for research purposes.[49] In May 1999, the WHA agreed to postpone the destruction of all variola stocks until 2002.[34] In 2005, the WHA again voted not to destroy smallpox stocks.[70] Most recently, in May 2011, the WHA agreed to postpone setting a date for destruction of smallpox stocks.[71,77] It is to be considered again at the 67th WHA meeting in 2014. At the present time, research using the virus is being conducted in the United States and Russia. This research is related to the development of safer vaccines and to antiviral agents.

In the early 1990s, evidence revealed that during the previous 10 years, the Soviet government apparently had developed a successful program to produce variola virus for use as a biologic weapon.[46,69] In the late 1990s, concern increased with regard to bioterrorism and, in particular, with the possibility that Russian expertise and equipment could have fallen into non-Russian hands because financial support for laboratories and workers had declined.

Smallpox was used as a biologic weapon almost 250 years ago.[24] In the French and Indian Wars (1754 to 1767), British forces sent smallpox-contaminated blankets and handkerchiefs to the Native Americans surrounding Fort Pitt in the summer of 1763.

ETIOLOGY

Smallpox is caused by a variola virus, an orthopoxvirus.[31,45,62] The virus particles are brick shaped and measure 250 to 300 × 200 to 250 × 100 nm; the size and shape are similar for all orthopoxviruses. The distinctive appearance is helpful in rapidly identifying members of this virus group by electron microscopy of vesicular fluid or crusts. The virus is stable when dried and may remain viable for long periods in dried crusts and indefinitely under freeze-drying techniques in the laboratory. It is propagated readily on the chorioallantoic membrane of embryonated eggs and in a variety of mammalian cell cultures.

EPIDEMIOLOGY

In infected patients, variola virus was found in respiratory secretions and in vesicular fluid from skin lesions. Transmission usually occurred after close personal contact, but airborne spread also could occur.[5,45,46,74] Patients with

smallpox were most infectious from the onset through the first 7 to 10 days of rash.

All persons were susceptible to smallpox unless they previously had been infected with variola virus itself or with cowpox or vaccinia virus. Thus, the occurrence of smallpox depended entirely on the presence of a human source of infection and effective exposure of susceptible persons. The age distribution of cases varied in individual countries, depending largely on vaccination practices. Preschool-aged children often were not vaccinated and thus had the greatest prevalence of disease.

The seasonal influence was substantial and perhaps is shown best by the spread of disease after the winter and spring introduction of smallpox into Europe; spread of infection was more than 30 times as great after the introduction of infection into European nations between December and May, in contrast to substantially less frequent spread after introduction between June and November.[79]

Substantial contrast in case-fatality rates was recognized in different geographic areas; these differences did not seem to depend on the supportive care available and did not appear to be related to ethnic or specific resistance factors. The only logical explanation for these different rates was substantial differences in the virulence of the virus prevalent in the regions. The mildest form of smallpox, described as *variola minor*, or *alastrim*, was prevalent in Brazil, Ethiopia, and adjacent countries. Case-fatality rates of 1 percent or less were customary, and permanent residual scarring and blindness were most unusual occurrences. In other areas of Africa and Indonesia, the disease appeared to be of intermediate severity, whereas on the Indian subcontinent, case-fatality rates were as high as 30 percent, with residual permanent scarring, blindness, and other sequelae occurring frequently in those who survived the acute illness.[32]

PATHOLOGY

The characteristic pathologic lesions affected the skin and mucous membranes. They involved the deeper layers of the skin and progressed through macular, papular, vesicular, and pustular stages, with the subsequent formation of crusts. Lesions similar to those on the skin also were found in the lower respiratory and gastrointestinal tracts.

Secondary bacterial infection occurred frequently and often affected the skin and lungs. Hemorrhagic complications (hemorrhagic smallpox) were not uncommon events.

CLINICAL MANIFESTATIONS[28,45,53,61]

After an incubation period of 7 to 17 days, the disease began abruptly with fever (i.e., temperatures between 38.9° and 40.5°C [102° and 105°F]), headache, and marked malaise.[8] Backache and muscle pain were prominent symptoms. Nausea, vomiting, and abdominal pain also were present.

After these prodromal signs and symptoms were present for 2 to 4 days, the fever usually decreased, and the characteristic cutaneous eruption appeared. The rash was most extensive on the face and extremities, and the individual lesions passed through the stages of macules and papules; by the third or fourth day, they clearly were vesicular. Lesions in a single area of the body were characteristically at the same stage of development.

By the sixth day, the vesicular fluid usually was cloudy and the individual pustules frequently were umbilicated. Pustules often converged and become confluent. By the 10th day, the individual lesions began to dry and formed characteristic crusts that remained intact for several days before they were shed. The patient's temperature customarily fell during the early appearance of the rash, although the fever usually returned. Significant fever that persisted after the 10th or 12th day of disease suggested the presence of bacterial superinfection.

Although most cases were similar to this description, which was characteristic of the ordinary type of smallpox, other clinical variations were described. The hemorrhagic type was the most severe form, with a case-fatality rate that approached 100 percent. In this form, hemorrhagic manifestations appeared during the prodromal stage, with extensive cutaneous extravasation of blood and bleeding from the various body orifices. Death usually occurred within the first week of illness, and, frequently few typical diagnostic lesions appeared on the skin surfaces before death ensued. Fortunately, this form of disease occurred in only 2 or 3 percent of the total cases of variola major in Asia, and it rarely was seen elsewhere.

A flat variety had been reported in approximately 6 percent of cases observed in India. In this variety, the cutaneous lesions remained flat and soft to the touch, in contrast to the ordinary variety; these lesions characteristically resolved without pustulation. This form was associated with case-fatality rates of 75 to 96 percent.[32]

A modified form of disease occurred almost exclusively in previously vaccinated persons. Although the prodromal illness often was severe, skin lesions were few, evolved rapidly, and were more superficial. The prognosis was excellent.

The mildest form of the disease, alastrim, or variola minor, was caused by a specific variola virus having less pathogenicity in humans. Serious forms of the illness, as with variola major, were unusual occurrences. The skin lesions tended to be superficial, and the clinical course resembled that of varicella, with the exception of the distribution of cutaneous lesions. These lesions involved the face and extremities, in contrast to the characteristic central body distribution of varicella. Residual scarring, if it occurred at all, usually reflected secondary bacterial infection of individual lesions.

In recently vaccinated persons, asymptomatic infection with variola virus after exposure had been demonstrated by increases in antibody titer against the virus when acute and convalescent sera were tested. This uncommon event was of neither clinical nor epidemiologic significance.

Complications included hemorrhagic events and various secondary bacterial infections, including impetigo,

pneumonia, empyema, and otitis media. Nephritis and arthritis with permanent joint changes were described.

DIFFERENTIAL DIAGNOSIS

The typical course, the characteristic cutaneous lesions, and the presence of other cases after contact 7 to 17 days earlier left little doubt about the etiologic agent. Varicella presented the greatest problem in differential diagnosis, particularly from the variola minor, or alastrim, form of the disease, but the distribution of cutaneous lesions for each condition was characteristic. Generalized vaccinia or eczema vaccinatum was distinguished by a history of exposure to vaccinia virus, previous skin lesions, and the distribution of the rash. Impetigo (especially the bullous variety caused by staphylococcal infection), scabies, secondary syphilis, and yaws were other considerations. Usually, little difficulty was encountered clinically in distinguishing among these infections.

Monkeypox can be clinically similar to smallpox, and, therefore, specific laboratory procedures are required for diagnosis (see Chapter 163). Other conditions included in the differential diagnosis were erythema multiforme, pityriasis rosea, measles, rickettsialpox, disseminated herpes simplex infection, syphilis, enteroviral exanthems, and bacterial, viral, and rickettsial petechial and purpuric rashes.

SPECIFIC DIAGNOSIS

Several laboratory procedures are available to provide specific and accurate diagnosis. Vesicular fluid, crusts, or scrapings from skin lesions reveal the characteristic brick-shaped viral particles of the variola-vaccinia virus group when examined by electron microscopy. These orthopoxviruses differ in appearance from the herpesviruses, which in the past were the agents most frequently confused with smallpox. Electron microscopy is precise and rapid and is preferred when facilities for this examination are available.[23] Smallpox virus DNA also can be identified rapidly by polymerase chain reaction (PCR).[28,29,52,66] PCR has an advantage over electron microscopy in that it can specifically distinguish smallpox virus from the orthopoxviruses.

Orthopoxviruses may be recovered and propagated on the chorioallantoic membrane of embryonated eggs or in tissue culture.[28] Virus recovery requires more time (3 to 7 days) than the direct antigen-detection tests, but it provides the specific active virus required for differentiation among the various orthopoxvirus types.[63,65] Infection also can be determined serologically by using acute-phase and convalescent-phase sera in enzyme-linked immunosorbent assay (ELISA), Western blotting, or virus neutralization assays.[28]

The specific diagnosis of a disease that does not currently exist anywhere in the world presents unique challenges. Recognizing these challenges, the CDC has a diagnosis and evaluation plan with laboratory testing recommendations (http://emergency.cdc.gov/agent/smallpox/diagnosis).

TREATMENT

Therapy primarily was supportive and symptomatic. The skin was kept clean, the bed linen was changed at regular intervals, and local or systemic therapy was provided for the frequent bacterial complications. Attention given to appropriate fluid and nutritional support was required.

Methisazone, convalescent smallpox serum, and vaccinia immune globulin (VIG) were effective in preventing the disease after exposure, but no evidence showed that these agents altered the course of the disease once symptoms occurred.[51] Idoxuridine was used for corneal lesions.[4]

At the present time the United States has a stockpile of VIG, which is produced by Cangene Corporation in Canada (http://www.cdc.gov/laboratory/drugservice/formulary.html).[76] This product is presently available for the treatment of smallpox vaccination complications (i.e., eczema vaccinatum, vaccinia necrosum, or severe generalized vaccinia). In the event of a biological terrorism smallpox release, it is assumed that VIG would be available for treatment.

Studies with the antivirals cidofovir and ST-246 show broad antiviral activity against orthopoxviruses.[1,20,61] Through the *Project Bioshield Act* of 2004, 1.7 million doses of ST-246 have been stockpiled.

PREVENTION

Active Immunization

In the 20th century, many strains of vaccinia virus were used in the effective prophylaxis of smallpox, which led to the control and then eradication of smallpox from the world. After smallpox was eliminated from the United States and Western Europe, general concern shifted to morbidity and mortality resulting from smallpox vaccines.[38,56,57] It was realized that the risk for smallpox was remote and that vaccine reactions were significant (Table 162-1). Because of this, routine smallpox vaccination was discontinued in the United States in the 1970s.

In the late 1990s, concerns arose that smallpox could be used as a weapon of bioterrorism. The events of September 11, 2001 and immediately thereafter highlighted the potential reality of this threat.* Estimates were that probably less than 20 percent of the U.S. population had any immunity.[43] These concerns led to recommendations by the Advisory Committee on Immunization Practices (ACIP) for the use of smallpox vaccine to protect persons who may need to work with orthopoxviruses and to prepare for a possible bioterrorism attack.[13] The government took steps to prepare the country in the event of a bioterrorist attack involving smallpox. These measures included building an adequate supply of vaccine, enhancing the laboratory capacity for diagnosis of variola and vaccinia virus infection, and training health care and public health personnel.[37]

From Lane JM, Ruben FL, Neff JM., et al. Complications of smallpox vaccination, 1968: results of 10 statewide surveys. *J Infect Dis* 1970;**122**:303–9.

*Rates of overall complications by age group include complications not provided in this table, including severe local reactions, bacterial superinfection of the vaccination site, and erythema multiforme.

†No instances of this complication were identified during the 1968 10-state survey.

Through the *Project BioShield Act*, the United States has an ample supply of smallpox vaccine.[64] This is presently available for immunization of selected people (e.g., first responders and laboratory workers) and would be available if a bioterrorist attack were to occur. This stockpile includes ACAM 2000, which is prepared in cell culture, and a modified vaccinia, Ankara (MVA), a new vaccine. This vaccine is thought to be safer than conventional smallpox vaccines and it was purchased by the United States to be used in immunocompromised persons if a terrorist smallpox release occurred.[42,44]

The primary strategy used in the past to control an outbreak of smallpox and to interdict the transmission of virus was known as a *surveillance and containment (ring vaccination)* strategy. This strategy identified infected persons through intensive surveillance and subsequently both isolated the individuals with the disease and vaccinated household and close contacts of the infected patient. Vaccination also was recommended for contacts of the primary contact with the patient (secondary contacts). This strategy was instrumental in the eradication of smallpox as a naturally occurring disease. Depending on the size of any smallpox outbreak and the availability of resources for rapid and thorough contact tracing, ring vaccination was supplemented previously in areas with identified smallpox cases to include voluntary vaccination of all individuals without vaccine contraindications. This strategy was pursued to expand the ring of immune individuals within an outbreak area and to reduce further the chance of any secondary transmission of smallpox to patients before they could be identified and isolated.

The CDC developed protocols to permit rapid, simultaneous delivery of smallpox vaccine to every state in U.S. territory within 12 to 24 hours. Smallpox response planning at the federal level has been conveyed to state and local health departments to address the rapid distribution of the vaccine if vaccination programs are suggested.

The CDC currently recommends that cases of febrile rash illnesses for which smallpox is considered in the differential diagnosis be reported immediately to local or state health departments or both. After evaluation is performed by local or state health departments, if smallpox laboratory diagnostics are considered necessary, the CDC Rash Illness Evaluation Team should be consulted. At this time, laboratory confirmation for smallpox is available routinely only at the CDC. Both a clinical consultation and a preliminary laboratory diagnosis can be completed within a period of 8 to 24 hours.

In the present bioterrorism era the CDC and the ACIP have devoted considerable effort into the diagnosis of smallpox and have looked at risks and benefits of smallpox immunization programs. To assist public health and other medical personnel in evaluating the possibility of smallpox in patients with febrile rash illnesses, the CDC developed a rash illness assessment algorithm (http://emergency.cdc.gov/agent/smallpox/diagnosis/riskalgorithm/).

Medical evaluation of the risks for acquiring smallpox under current conditions and in the absence of a case of smallpox or a confirmed smallpox bioterrorism threat in contrast to the potential risks for developing vaccine complications was such that the ACIP concluded that vaccination of the general population was not recommended because the potential benefits of vaccination did not outweigh the risks for vaccine complications. In 2001, the ACIP recommended smallpox vaccine for laboratory workers who directly handle (1) cultures or (2) animals contaminated or infected with vaccinia, recombinant vaccinia viruses, or other orthopoxviruses that infect humans (e.g., monkeypox and cowpox).[13] Other health care workers (e.g., physicians and nurses) whose contact with these viruses is limited to contaminated material (e.g., dressings) but who adhere to appropriate infection control measures are at lower risk for inadvertently acquiring infection than are laboratory workers. However,

because a theoretical risk for developing infection does exist, vaccination may be considered for this group. Because of the low risk for developing infection, vaccination was not recommended for persons who do not handle virus cultures or materials directly or who do not work with animals contaminated or infected with these viruses. According to available data on the persistence of neutralizing antibody after vaccination, persons working with vaccinia, recombinant vaccinia viruses, or other nonvariola orthopoxviruses should be revaccinated every 10 years.

In 2003, the ACIP and the Healthcare Infection Control Practices Advisory Committee (HICPAC) published supplemental recommendations for using smallpox vaccine in a pre-event vaccination program.[15] A summary of these recommendations is presented here:

To facilitate preparedness and response, smallpox vaccination is recommended for persons designated by public health authorities to conduct investigation and follow-up of initial smallpox cases that could necessitate direct patient contact.[15] The ACIP recommended that each state and territory establish and maintain more than one smallpox response team. The ACIP and the HICPAC recommended that each acute-care hospital identify health care workers who can be vaccinated and trained to provide direct medical care for the first smallpox patients requiring hospital admission and to evaluate and manage patients who are suspected as having smallpox. When feasible, the first-stage vaccination program was to include previously vaccinated health care personnel to decrease the potential for adverse events. Additionally, persons administering smallpox vaccine in this pre-event vaccination program were to be vaccinated.

Side Effects and Adverse Events of Smallpox Vaccines

The risk for adverse events resulting from smallpox vaccine today is presumed potentially to be at least as great, in terms of severity and frequency of events, as during the era when universal vaccinia vaccination was performed.[16,38] One can suspect that the number of adverse reactions may be increased in frequency in the current era in contrast to the 1960s and 1970s because a larger proportion of the population of the United States and the world may have an inherited or acquired a form of immunodeficiency or may be receiving a variety of agents that suppress the immune system. Factors thought to predispose to development of adverse events include pregnancy or breast-feeding, extensive skin eruptions, atopic dermatitis, T-cell immune defect, immunosuppressive therapy, inflammatory or disruptive diseases of the cornea, and age younger than 1 year.[16]

Fever occurs commonly after smallpox vaccination. As many as 70 percent of children have 1 or more days with a temperature of 37.8° C (100° F) or higher 4 to 14 days after receiving primary vaccination,[18,59] and 15 to 20 percent have temperatures of 38.9° C (102° F) or higher. After receiving revaccination, 35 percent of children have temperatures of 37.8° C (100° F) or higher, and 5 percent have temperatures of 38.9° C (102° F) or higher.[59] Fever after vaccination or revaccination occurs less commonly in adults than in children.

An erythematous or urticarial rash may occur approximately 10 days after receipt of primary vaccination. The vaccinee usually is afebrile, and the rash resolves spontaneously within 2 to 4 days. Rarely, bullous erythema multiforme (Stevens-Johnson syndrome) occurs.[53]

Inadvertent inoculation at other sites, the most frequent complication of vaccinia vaccination, accounts for approximately half of all complications of primary vaccination and revaccination.[17] Inadvertent inoculation usually results from autoinoculation of vaccine virus transferred from the site of vaccination. The most common sites involved are the face, eyelid, nose, mouth, genitalia, and rectum. Most lesions heal without specific therapy, but VIG may be useful for cases of ocular implantation.

Generalized vaccinia in persons who have no underlying illness is characterized by a vesicular rash of varying extent. The rash generally is self-limited and requires little or no therapy, except in patients whose conditions appear to be toxic or in those who have a serious underlying illness.

Other expected systemic symptoms associated with smallpox vaccination include malaise, myalgia, headache, chills, nausea, and fatigue (0.3% to 37%).[35,36] Soreness at the site of the vaccination is a very common development, as are local lymphadenopathy and erythema surrounding the vaccination site.[37]

Expected local events occurring relatively infrequently require symptomatic treatment. They include satellite lesions within 2.5 cm of the primary lesion, viral lymphangitis, local edema, and intense inflammation surrounding the papule.[35-37]

More severe complications of vaccinia vaccination include eczema vaccinatum, progressive vaccinia, myopericarditis, and postvaccinial encephalitis. These complications, with the exception of myopericarditis, occur at least 10 times more often among primary vaccinees than among revaccinees and more frequently among infants than among older children and adults.[55-57]

The number of adverse events per million doses of primary smallpox vaccination and revaccination is reported in Table 162-1. The rates described are based on surveys of vaccination-associated complications that occurred in the late 1960s in the United States. The high prevalence of immunosuppression in the United States today in contrast to the late 1960s may render the rates of vaccinia necrosum higher than in 1968. The rate of postvaccinial encephalitis in adults was difficult to document in the 1960s because very few adults were primary vaccinees. Studies performed in Europe showed higher rates of postvaccinial encephalitis in adults than in young children. Studies performed since 2002, when efforts were made to vaccinate members of the military and civilians, have shown similar rates of adverse reactions, although cardiac side effects have been more notable (Table 162-2).

Eczema vaccinatum is a localized or systemic dissemination of vaccinia virus in persons who have eczema or a history of eczema and other chronic or exfoliative skin conditions (e.g., atopic dermatitis). The illness often is

TABLE 162-2 Number of Reported Events Associated with Smallpox Vaccination in the Military: 2002 to 2007

Event Type	Department of Defense Experience*	Grabenstein and Winkenwerder†
Inadvertent inoculation	61	Self: 48 Transfer to contact: 21
Generalized vaccinia	43	36
Eczema vaccinatum	1	0

Treated with VIG	6	N/A
Death‡	8	0

*Department of Defense experience: December, 2002 to May, 2007, 1,200,000 million vaccinees.[28]
†Experience of U.S. military: December, 2002 to May, 2003, 450,293 vaccinees.[50]
‡After review, one death was the result of an acute lupus-like illness that may have been caused by the vaccine, and others were thought to result from other causes.[28]
NA, Not applicable; *VIG,* vaccinia immune globulin.

mild and self-limited but may be severe and occasionally fatal. The most serious cases in vaccine recipients occur in primary vaccinees and appear to be independent of the activity of the underlying eczema.[73] Severe cases also have been observed after contact infection has occurred.

Progressive vaccinia (vaccinia necrosum) is a severe, potentially fatal illness characterized by progressive necrosis in the area of vaccination, often with metastatic lesions. It occurs almost exclusively in persons with cellular immunodeficiency.

In the 1960s, cardiac complications were reported but were not considered significant. Myopericarditis now is thought to be a true adverse event related to smallpox vaccine, although most cases resolve without further complications.[9,27] Cases of ischemic heart disease occurring after receipt of smallpox vaccination also have been reported. Although this association has not been shown to be causal, the ACIP recommended excluding persons with cardiac disease from participation in current smallpox vaccination programs.[15] The incidence of cardiac events in children is not known because the recent vaccination program has targeted adults.

The most serious complication is postvaccinial encephalitis. Usually, it affected primary vaccinees younger than 1 year of age. Of affected vaccinees with this complication, 15 to 25 percent died and 25 percent had permanent neurologic sequelae.[40,56,57]

Death rarely occurred after receipt of vaccinia vaccination; reports note approximately one to two deaths per million primary vaccinations and 0.1 death per million revaccinations. Death most often was the result of postvaccinial encephalitis or progressive vaccinia.

Vaccinia may be transmitted when a recently vaccinated person has contact with a susceptible person. In the CDC's 10-state survey of complications of smallpox vaccination, the risk for transmission to contacts was 27 infections per million total vaccinations; 44 percent of these contact cases occurred in children 5 years of age or younger.[57] Since 1980, several cases of contact transmission of vaccinia from vaccinated military recruits have been reported and include six cases transmitted by a single vaccine recipient.[10-12]

Since 2001, among 1,200,000 vaccinated military personnel, 61 suspected instances of transfer of vaccinia occurred, 36 of which were laboratory confirmed.[25] This number included two cases of tertiary transfer, one from a service member to his wife and then to their breastfeeding baby and another among male sports partners.[15,37] Fetal vaccinia occurs rarely (<40 reported cases), but usually it is fatal.[38]

More than 60 percent of cases of contact transmission result in uncomplicated inadvertent inoculation. Approximately 30 percent of these cases result in eczema vaccinatum, which may be fatal.[57] Eczema vaccinatum may be more severe in contacts than in vaccinated persons, possibly because of simultaneous multiple inoculation at several sites.[21,56] Contact transmission rarely results in postvaccinial encephalitis or vaccinia necrosum.

Smallpox Vaccine Availability

The CDC is the only source of smallpox vaccine and VIG for civilians. In the advent of need to carry out smallpox vaccination, procedural information will be available from the CDC.

CHAPTER 163

Monkeypox and Other Poxviruses

Samantha H. Johnston • Anne W. Rimoin

Smallpox, caused by variola virus (see Chapter 162), at one time was the most important human poxvirus disease, but this disease has been eradicated from the world. Today, only one human poxvirus, molluscum contagiosum virus, causes specific human illness. In addition, at least nine other poxviruses can cause human infections. Eight of these viruses are acquired zoonotically, and the other, vaccinia, is acquired by active immunization against smallpox, inadvertently by laboratory accident, or from a vaccinated person to an unvaccinated person.

PROPERTIES OF THE VIRUSES

Classification

The family *Poxviridae* has two subfamilies: *Chordopoxvirinae* (vertebrate poxviruses) and *Entomopoxvirinae* (insect poxviruses).[45,48,93] Eight genera are included in the *Chordopoxvirinae* subfamily, and four of these genera contain species that infect humans (Table 163-1).

Structure

Poxviruses are the largest animal viruses and are discernible by light microscopy.[11,95] In general, by electron microscopy, orthopoxviruses appear brick shaped, with a length of 350 nm and a width of 270 nm. They contain double-stranded DNA genomes that vary from 130 to 300 kbp, depending on the particular species. A 30-nm lipoprotein bilayer (envelope) surrounds the virus core. The envelope contains seven or more distinct glycoproteins. *Parapoxvirus* organisms have a different structure than do *Orthopoxvirus*, *Yatapoxvirus*, and *Molluscipoxvirus* organisms. They are ovoid and vary from 260 to 160 nm for orf virus to 300 to 190 nm for pseudocowpox virus.

SPECIFIC VIRUSES AND THEIR ILLNESSES

Monkeypox Virus

Monkeypox is a zoonotic orthopoxvirus that causes a serious smallpox-like illness in humans.* Monkeypox virus was first discovered in 1958, when it was isolated from the lesions of a generalized smallpox-like vesiculopustular disease among captive monkeys at the State Serum Institute in Copenhagen, Denmark.[130] The disease was not recognized as being distinct from smallpox until 1970, when, after smallpox had been eliminated from many countries, a similar illness continued to circulate in rural regions of the Democratic Republic of Congo (DRC).[39,61,68,95] Between 1970 and 1979, 55 cases of monkeypox were confirmed by the World Health Organization (WHO) in forested areas of Western and Central Africa, of which 44 cases (80%) occurred in the DRC.[10,69,82]

In 1980, smallpox was declared eradicated by the WHO Advisory Committee on Orthopoxvirus Infections. Despite sporadic reports of human monkeypox in Africa, the WHO Advisory Committee also recommended that smallpox vaccination cease globally because of the cost and complexity of sustaining a special vaccination program for what was then a comparatively rare disease.[134] To address the concern that in the absence of smallpox vaccination campaigns, monkeypox might have the potential to emerge from central Africa and occupy the niche vacated by smallpox, a WHO-sponsored active surveillance program was carried out in selected districts in the DRC from 1981 to 1986.[108] This surveillance program initiated modeling of monkeypox human-to-human transmission patterns. Models predicted that the reproductive number (R_o) was less than 1 and that human-to-human transmission was at low enough levels not to present a significant public health threat. Thus, the WHO recommended against sustained vaccinia vaccination for protection against monkeypox.[58,134]

During this period 338 cases were identified. Most cases were found in children (mean age, 4.4 years), leading to the hypothesis that smallpox vaccine may confer a degree of immunity in adults.[68,92,95] Since the WHO's initial efforts in monkeypox surveillance were initiated, outbreaks, mostly in the DRC, have been reported in the literature. Monkeypox has since supplanted smallpox as the most important orthopoxvirus affecting humans, and more attention has been directed to understanding the transmission patterns, epidemiology and control strategies of this illness.

Epidemiology

Epidemiologic studies beginning in 1970 identified several outbreaks of human monkeypox, with most cases arising in the DRC. Jezek and associates[72,74] reported disease in 338 patients and found that among patients with primary infection (i.e., cases associated with an animal source), 50 percent were younger than 4 years of age and 93 percent were younger than 14 years of age. Ninety-six percent of these children were not vaccinated against smallpox.[10] Animal sources were suspected in 245

*References 9, 10, 14, 22-28, 39, 61, 62, 68, 73, 74, 78, 92, 94, 95, 103.

TABLE 163-1 **Poxviruses That Can Cause Human Illness**

Genus	Species
Orthopoxvirus	Variola virus
	Monkeypox virus
	Vaccinia virus
	Cowpox virus
Parapoxvirus	Orf virus
	Bovine papular stomatitis virus
	Pseudocowpox virus
	Parapox of seals
	Parapoxvirus of reindeer
Yatapoxvirus	Tanapoxvirus
	Yabapoxvirus
Molluscipoxvirus	Molluscum contagiosum virus

of the 338 cases, and human-to-human transmission occurred in the remaining 93 cases. Analysis of unvaccinated contacts of the patients showed a secondary attack rate of 9.3 percent.[10] The longest chain of infection was four generations.[72] Index cases of monkeypox were usually women or children who had frequent contact with animals.[26,35] Since initial pox lesions on the hands or arms indicative of direct inoculation were not described, infection was presumably acquired by inhaling material aerosolized during handling or butchering of an animal. Person-to-person transmission was generally limited to family members and other close contacts, suggesting monkeypox was less transmissible than smallpox, but the small size and low population density of rural villages also may have helped limit the size of outbreaks.[35]

At the end of the active WHO surveillance program in 1986, only 13 cases of human monkeypox were reported until 1995, likely as a result of political instability in the region. In 1996 to 1997, the largest outbreak ever recorded occurred in the Kasai Oriental region of the DRC. During an initial investigation by the WHO and the Centers for Disease Control and Prevention (CDC), 92 cases were identified and a follow-up investigation suggested an additional 419 suspected cases. However, confusion with a concurrent varicella outbreak made precise estimates of the true outbreak size difficult to ascertain.[21,58] Analysis of 320 possible and probable cases showed attack rates of 18 percent in susceptible individuals, 3 percent if vaccinated, and 26 percent if unvaccinated.[58] Eighty-five percent of cases occurred in patients younger than 16 years of age. The case-fatality rate was 1.5 percent, lower than the previously reported rate of 10 percent.[21] The broad case definition used for monkeypox case identification of fever and vesiculopustular rash possibly could include infections with varicella as well, thus artificially increasing the rates of reported secondary transmission as well as artificially decreasing the case-fatality rates.[39]

Meyer and colleagues[92] used viral isolation and amplification by polymerase chain reaction (PCR) to detect monkeypox virus after a 2001 outbreak in the DRC. The group found that coinfection and cotransmission of varicella could have misrepresented actual cases of monkeypox. Of the seven small outbreaks, two were proved to be the result of monkeypox (16 cases, 4 deaths); two showed evidence of co-circulating monkeypox and varicella (7 cases, 1 death); two were the result of varicella-zoster virus (6 cases, 0 deaths); and neither virus was isolated in the final outbreak. Children were the principal victims in all outbreaks.

Rimoin and colleagues[108] conducted active surveillance for human monkeypox in the DRC between 2005 and 2007 to assess the current burden of infection and noted a dramatic increase in monkeypox cases since the 1980s. The most heavily affected health zones showed a 20-fold increase in monkeypox activity in contrast to the 1980s, with an increase in cases from 0.72 to 14.42/10,000. Ninety-two percent of cases occurred in those born after smallpox vaccination ended in 1980. The study concluded that risk for monkeypox is "inversely associated with smallpox vaccination."

These surveillance activities have supported the three main factors determining monkeypox burden in enzootic areas: smallpox vaccination, exposure to animal reservoir species, and human-to-human transmission of disease. Smallpox vaccination officially ceased in the DRC in 1982; thus, vaccine-induced herd immunity has waned, partially contributing to increased incidence.[78] Another contribution has been the change in animal contact during this time period. Monkeypox generally occurs in villages in or near tropical rainforest. Clearing of these forests as well as increased reliance on reservoir species for nutrition likely has brought humans into closer contact with reservoir species.[108] The effect of increased human-to-human transmission has not been formally investigated, but waning immunity to smallpox is thought to allow more sustained transmission of monkeypox in a generally naïve population.

Although monkeypox outbreaks in humans had been reported during the 1970s, few cases have been noted outside of DRC.[6,104] However, serologic evidence shows that orthopoxvirus, presumably monkeypox, may be circulating in West Africa among multiple species, including humans.[89,105]

Only one known outbreak has occurred outside of Africa. In May of 2003, the CDC reported the first outbreak of monkeypox in humans in the Western Hemisphere among 47 patients with laboratory-confirmed or probable cases.[13,22,23-25,106] No case fatalities and no cases of secondary transmission occurred. Fourteen cases resulted in hospitalization, two of these were severe cases in children. One girl developed encephalitis that resolved over the course of a 14-day hospitalization; a second girl developed diffuse oral and pharyngeal lesions that impaired swallowing, and she also recovered.[23] The outbreak was linked to the distribution of North American prairie dogs as pets that had become ill after being housed with an infected rope squirrel and an infected giant pouched rat shipped from Ghana. Patients were identified in Illinois, Indiana, Kansas, Missouri, Ohio, and Wisconsin.[12,23-25,63,103] PCR analysis of tissue obtained from the prairie dogs revealed 100 percent similarity with the monkeypox virus strain Zaire 96-I-16 that had been isolated previously from the DRC.[79]

The virus is thought to spread to humans by handling of infected animals or by direct contact with an infected animal's body fluids or lesions.[79] Person-to-person spread occurs by large respiratory droplets, although monkeypox transmission is much less efficient than smallpox.[26,95,114] A risk factor for secondary transmission is close contact with a primary case. Evidence of previous vaccination is thought to be protective, with surveillance programs estimating vaccine efficacy between 80 and 85 percent.[34,49,108] Mortality rates have varied between 0 and 17 percent during outbreaks.*

Serologic evidence suggests that many animals, including both arboreal and terrestrial rodents and nonhuman primates, can be infected with monkeypox virus, however, rope squirrels have been targeted as the primary host.[39,52,63] Epidemiologic studies from the DRC have implicated squirrels living in agricultural areas as primary candidates to sustain transmission among people in nearby settlements, although no definitive host has been identified. Concerns that monkeypox virus could spread through North American rodent populations and serve as a vector for continued zoonotic exposure have not played out.[39]

Clinical Features

The clinical features of human monkeypox virus infection are similar to those of smallpox, but the overall illness tends to be less severe. The characterization of symptoms during outbreaks in Africa has been limited by poor access to medical care, retrospective identification, and civil unrest in areas of outbreaks. The outbreak reported in the midwestern United States allowed researchers to describe clinical and laboratory parameters of disease.[63]

After a 10- to 14-day period of incubation (range, 1 to 31 days), a 2-day prodrome of fever, malaise, and lymphadenopathy precedes the manifestation of rash.[10,39,68] Lymphadenopathy occurs in 90 percent of unvaccinated individuals and is a key feature distinguishing monkeypox from smallpox because lymphadenopathy generally does not occur in smallpox. Affected lymph nodes may be unilateral or bilateral and include submandibular, cervical, postauricular, axillary, inguinal, or any combination of these locations.[9] Other signs and symptoms include chills, sweats, headache, backache, sore throat, cough, and shortness of breath.

The rash usually appears first on the face. As in smallpox, lesions develop and progress together in the same body region through the stages of macules, papules, vesicles, and pustules. Over the course of a 2- to 4-week period, the lesions progress until they finally scab over and desquamate. Most patients have discrete lesions, and it is estimated that 23 percent have semiconfluent lesions and 7 percent have confluent lesions. Mucous membrane involvement and conjunctivitis are common manifestations.[74,92] Lesions usually are found on the extremities, head, and trunk, as well as on the palms and soles.[61] During the first week of the rash, patients are considered to be infectious.[73] Cases without rash have been described.[84] The presence of rash on the palms and soles and the stages of progression of the rash distinguish this from varicella.

Complications include secondary bacterial infection of the skin; pneumonia; vomiting, diarrhea, and dehydration; keratitis and corneal ulceration; septicemia; and encephalitis. The death rate in nonvaccinated patients was 11 percent in the study reported by Jezek and associates,[74] and all deaths occurred in children aged 8 years or younger, possibly reflecting protective effect in older individuals who may have received vaccinia immunization.

One case of congenital monkeypox infection has been reported.[67] The child's mother presented with clinical characteristics of monkeypox on August 12, 1983, and the child was born prematurely on September 23, 1983. At birth, the child had generalized skin lesions and died 6 weeks later of malnutrition. No data are available on the clinical course of monkeypox in patients with human immunodeficiency virus and acquired immunodeficiency syndrome (HIV/AIDS) or other immunocompromised states.

Unlike African patients, in whom more severe illness is noted, most of the patients in the United States had what was described as a mild, self-limited febrile rash illness.[25] The majority of patients had localized lesions associated with direct contact with infected animals, and only one patient, a child, had a generalized rash. Nevertheless, the outbreak resulted in 14 hospitalizations among the 47 cases. Differences in the severity of disease may result from differences in virulence among genetically distinct clades of monkeypox viruses: the West African monkeypox virus group and the Congo basin isolates.[88] Congo basin isolates have been shown to be more virulent in nonhuman primates and based on epidemiologic and genetic sequence analyses are thought to be more virulent in humans as well.[30,45,68,90,113]

Laboratory alterations noted in patients of the midwestern U.S. outbreak included elevated transaminases in 50 percent of patients, low blood urea nitrogen (61%), hypoalbuminemia (50%), leukocytosis (45%), and thrombocytopenia (35%).[63]

Diagnosis

All suspect cases should be reported immediately to the local health department. Laboratory confirmation is required for establishing a definitive diagnosis. The CDC case definitions from 2004 can help guide clinicians (Table 163-2).[26] Samples used for diagnosis include blood and cutaneous tissue from at least two scabs that have been unroofed and collected in a sterile fashion. Once lesions have been unroofed, the base of the vesicle should be swabbed with sterile cotton or polyester swab and the material applied to a clean microscope slide and air-dried. The material should be sent to the CDC or a national reference laboratory in the country of origin for diagnostic testing. Other specimens used for analysis include skin biopsy specimens, which may be indistinguishable from those of smallpox lesions, with necrosis of the stratum basale, adjacent dermal papillae, and stratum spinosum.

*References 1, 7, 37, 50, 62, 68, 71, 73, 92.

TABLE 163-2 **Centers for Disease Control and Prevention Case Definition for Human Cases of Monkeypox (January 2004)**

Human Monkeypox Case Classification	Human Monkeypox Case Classification
Suspect Case The patient meets one of the epidemiologic criteria and has fever or unexplained rash and two or more other signs or symptoms with onset of first sign or symptom within 21 days after the last exposure. **Probable Case** The patient meets one of the epidemiologic criteria and has fever and vesicular-pustular rash with onset of the first sign or symptom less than 21 days after the last exposure meeting epidemiologic criteria; or if rash is present but type is not described, the patient demonstrates elevated levels of IgM antibodies reactive with orthopoxvirus between at least 7 and 56 days after the rash onset. **Confirmed Case** The patient meets one of the laboratory criteria. ***Clinical Criteria*** Rash (macular, papular, vesicular, pustular, generalized or localized, discrete or confluent) Fever (subjective or measured, ≥37.4°C) Other signs and symptoms (chills and/or sweats, headache, backache, lymphadenopathy, sore throat, cough, shortness of breath) ***Epidemiologic Criteria*** Exposure (includes living in a household, petting or handling, or visiting a pet-holding facility such as a pet store or veterinary clinic) to an exotic or wild mammalian pet (including prairie dogs, Gambian giant rats, and rope squirrels, among others to be considered on a case-by-case basis) obtained on or after April 15, 2003, with clinical signs of illness (e.g., conjunctivitis, respiratory symptoms, and/or rash)	Exposure (as described earlier) to an exotic or wild mammalian pet (as described earlier) with or without clinical signs of illness that has been in contact with either a mammalian pet (living in a household or originating from the same pet holding facility as another animal with monkeypox) or a human Exposure (skin-to-skin or face-to-face contact) to a suspect, probable, or confirmed human case ***Laboratory Criteria*** Isolation of monkeypox virus in culture Demonstration of monkeypox virus DNA by PCR testing of a clinical specimen Demonstration of virus morphologically consistent with an orthopoxvirus by electron microscopy in the absence of exposure to another orthopoxvirus Demonstration of presence of orthopoxvirus in tissue using immunohistochemical testing methods in the absence of exposure to another orthopoxvirus ***Exclusion Criteria*** An alternative diagnosis can explain the illness. *OR* The case was reported on the basis of primary or secondary exposure to an exotic or wild mammalian pet (as described earlier) or a human subsequently determined not to have monkeypox, provided other possible epidemiologic exposure criteria are not present. *OR* A patient without a rash does not develop a rash within 10 days of onset of clinical symptoms consistent with monkeypox. The case is determined to be negative for nonvariola generic orthopoxvirus by PCR testing of a well-sampled rash lesion by the approved protocol. The case is determined to have undetectable levels of IgM antibody 7 to 56 days after rash onset.

Modified from Centers for Disease Control and Prevention: Updated interim case definition for human monkeypox, Atlanta, 2004, CDC. Available at http://www.cdc.gov/ncidod/monkeypox/casedefinition.htm; and Centers for Disease Control and Prevention: *Update: multistate outbreak of monkeypox—Illinois, Indiana, Kansas, Missouri, Ohio, and Wisconsin, 2003.* MMWR Morb Mortal Wkly Rep 2003;**52**:561–4, 2003.
IgM, Immunoglobulin M; *PCR,* polymerase chain reaction.

Electron microscopy of the lesions shows abundant large, brick-shaped orthopoxvirus particles in the cytoplasm of infected epidermal cells.[122]

Blood samples may be analyzed for paired acute-phase and convalescent-phase serum samples; however, serologic testing is limited because of the close antigenic relationship that exists among orthopoxviruses. More specific methods used by the CDC include cell culture or chick chorioallantoic membrane isolation, along with PCR and sequencing to differentiate monkeypox virus from other orthopoxviruses.[35,81,86] PCR also can differentiate between Congo Basin and West African monkeypox strains.[87,112]

Treatment and Prevention

In 1968, investigators reported that monkeys could be immunized against monkeypox virus using smallpox vaccine.[90] In outbreaks in the DRC described by Jezek and colleagues, as well as by more recent surveillance by Rimoin and colleagues,[74,108] prior smallpox inoculation was found to be protective and result in a milder form of disease, often difficult to distinguish from chickenpox. Hammarlund and associates[56] also described protective immunity to monkeypox virus in persons previously vaccinated against smallpox. Vaccine efficacy was estimated to be 85 percent during surveillance trials in the 1980s and more than 80 percent for more than 30 years during more recent surveillance.[50,108] However, the smallpox vaccination status did not alter either the severity of illness or hospitalization rates in the midwestern U.S. outbreak.[61] The CDC recommended vaccination with smallpox vaccine for those without contraindications to vaccination, including health care workers and household contacts of patients with suspected or confirmed monkeypox cases. Preexposure vaccination is preferred, but vaccination can be administered after laboratory confirmation of an infection. Vaccination should be given within 4 days but may be considered protective up to 14 days after exposure.[26]

Because of the high frequency of complications associated with administering vaccinia, Stittelaar and colleagues[124] described the potential use of a modified vaccinia virus strain, Ankara, as safer vaccine against orthopox infections. Laboratory studies demonstrated that macaques given Ankara were protected against lethal respiratory challenges with monkeypox virus. This vaccine candidate, IMVAMUNE, was shown to be safe and provide immunity in humans; as of 2010 it had been granted fast track status by the U.S. Food and Drug Administration (FDA).[128] Another candidate, LC16m8, also underwent phase I and II clinical trials; it achieved antivaccinia, antivariola, and antimonkeypox neutralizing antibodies without any observed cardiac toxicities.[77] A variety of other vaccines have been studied in various primate models, and these have also shown promise.[37,43,59]

Important questions have been raised as to the risks and benefits of testing these vaccines for efficacy and vaccinating humans in monkeypox endemic areas.[107] These issues may become more relevant global public health issues should monkeypox become established in an animal reservoir outside of Africa.

Roess and colleagues[110] evaluated education-based prevention efforts in areas endemic for monkeypox; after a community intervention trial, they found improved disease recognition and transmission and risk-limitation methods in place. Until an effective and inexpensive monkeypox vaccine becomes available, this type of intervention may be the best option to provide some degree of disease prevention.[110]

As a potential preventive measure, 28 residents (26 adults and 2 children) affected in the U.S. outbreak area received a smallpox vaccine to try to prevent further transmission of monkeypox.[24] No data exist on the effectiveness of vaccinia immunoglobulin; however, it may be considered as a treatment for severe cases of monkeypox infection and as a prophylaxis in exposed persons who are severely immunocompromised.[39]

Additionally, cidofovir has been shown to be active in vitro and in vivo in animal models as a potential treatment,[2,36] but no reported data on its effectiveness for treating infected humans exists to date. However, the CDC recommends that it be considered as a treatment in severe monkeypox virus infections and in immunocompromised hosts, but should not be used as a prophylaxis because of its significant toxicities.[14] Tecovirimat, or ST-246, a compound with activity against orthopoxviruses, also has shown promise in treating severe monkeypox virus infection in rodent and nonhuman primate models and may one day be approved for use in humans.[76,115,121] Mitoxantrone, a drug already FDA approved for multiple sclerosis and cancer, recently demonstrated the ability to carry some antiviral effects against monkeypox and cowpox viruses, although less effectively than cidofovir.[1]

Among hospitalized patients, isolation precautions should be taken because the virus may be transmitted by direct contact or large respiratory droplets that may be airborne.[26] Isolation can be discontinued for patients with vesiculopustular rash after all lesions have crusted; however, contact with immunocompromised persons should be limited until all crusts have separated. For patients without rash, isolation should be continued for 7 days after the onset of fever. Asymptomatic contacts should remain under symptom surveillance for 21 days after the last exposure, and temperature should be monitored twice daily. Affected individuals should not donate any body fluids or organs while ill.[26]

Bioterrorism Concerns

Concern over monkeypox virus as an agent of bioterrorism has been raised, but there has been no evidence to suggest that the virus becomes more severe, virulent, or easily transmissible after passages through human hosts.[72] Furthermore, evidence that monkeypox evolved independently from smallpox alleviated some fears that the virus could "evolve back" into smallpox. Further, low rates of primary infection, limited transmissibility, and low case fatality make monkeypox an unlikely bioterrorist threat.[8] However, some concerns remain about the potential of molecular biologic techniques to manipulate the virus genetically into a more lethal form.[65,116]

Cowpox Virus

Cowpox disease has been recognized for hundreds of years in Europe. The infection causes ulcers on the teats of cows.[45] Those working with infected cows, including milkmaids, often developed similar ulcers on their hands and were known to be immune to smallpox. In May of 1796, this led Edward Jenner to inoculate James Phipps, an 8-year-old boy, with cowpox material obtained from a lesion on a local dairy maid.[6,66-68] No infection occurred after exposing him to material from a smallpox lesion.

Recent studies have found that the reservoir hosts are not cows, but instead wild rodents. Further, it is a rare illness with a geographic distribution throughout Western Europe.[4,6,11] Baxby[4] reported 12 human patients with illnesses caused by cowpox virus; only 5 were exposed to infected cows and the other 7 reported no direct contact with cows. All patients, however, lived in or had visited rural areas before the onset of illness. Of the 10 patients with lesions, 6 had lesions on the hand only, 3 had lesions on the chin or face only, and a single patient had lesions on both the face and hand. Most patients had local edema, lymphadenitis, and fever. Initially, lesions were confused with anthrax in two patients.

An additional 12 cases of cowpox causing cutaneous infection were reported from various European countries. Most identified cases resolved between 3 weeks to 6 months, but one fatality was reported. The authors reported a 7-year-old girl with persistent lymph node enlargement 2 years after initial presentation of infection. Patients developed infection after they had exposure to ill animals, including cats (9), dogs (2), and wild rats (1).[97] One immunocompromised 18-year-old man died; he was thought to have acquired the infection from a cat with a skin lesion on the anterior paw.[33] Schupp and associates[116] reported a single case of cowpox virus potentially from a cat, causing necrotic ulcers on a 12-year-old boy in Germany. The virus was isolated and detected by PCR.

Similar to monkeypox virus, several compounds have shown antiviral effects for cowpox virus in vitro or

in animal models. These include cidofovir, ST-246, terameprocol, and mitoxantrone.[3,100,102]

Vaccinia Virus

Vaccinia virus is the live immunizing antigen successfully used in the global program to eradicate smallpox. This orthopoxvirus is different from cowpox virus, the agent that Jenner and others used for vaccination in the early 19th century. Vaccinia virus has been used for vaccination for more than 100 years. Restriction endonuclease studies indicated that various strains of vaccinia virus from different geographic regions are similar to each other but distinctly different from cowpox virus.[45] The origin of vaccinia virus is unknown, but various hypotheses exist regarding its origin,[11] including (1) evolving from variola virus through continual passage in the skin of cows or humans, (2) evolving from cowpox virus through continual passage in the skin of animals, (3) hybridization between cowpox virus and variola virus, and (4) evolving in a an extinct natural animal host.

Vaccinia virus has caused outbreaks in several countries in milk herds; most commonly it has been reported in India and Brazil, with reports published since 1999. An outbreak in India was described in which infected buffaloes were thought to have had contact with vaccinated humans during smallpox eradication programs, rather than the virus being a primary buffalo pathogen.[11,45] In several Brazilian provinces, skin lesions on dairy cows and their milkers resembling cowpox were found to be caused by a variety of vaccinia virus strains belonging to two distinct groups. During the 18th and 19th centuries, cases with vaccinia virus were thought to have evolved from repeated introduction of vaccinia.[126] In addition to cutaneous symptoms, patients reported fever, malaise, myalgia, headache, cough, and adenopathy.[118] Secondary bacterial infection of cutaneous lesions has been reported.

Because of the success of the smallpox eradication program in the United States, routine vaccinia vaccination was discontinued in 1971,[19,20] and by 1976, the recommendation of vaccinating health care workers also was discontinued.[15] However, in 1980, the Advisory Committee on Immunization Practices (ACIP) recommended vaccinating laboratory workers to protect them from possible infection while working with nonvariola orthopoxviruses (e.g., vaccinia, monkeypox, and recombinant vaccinia).[16,51,57]

In 1982, the only active licensed producer of vaccinia vaccine in the United States ceased production for general use, and distribution to civilian populations was discontinued in 1983.[18] However, the CDC has continued to provided vaccinia vaccine for laboratory workers.[17] In 1984, the laboratory recommendations were formally included in guidelines for biosafety in microbiologic and biomedical laboratories. This was expanded to include persons working in animal care areas where studies with orthopoxviruses were performed.[127]

Since January of 1982, smallpox vaccination has not been required for international travelers, and International Certificates of Vaccination no longer include smallpox vaccination.[135] Military personnel continued to be vaccinated routinely for several years after discontinuation. More recently, only selected groups of military personnel are vaccinated against smallpox; groups include those designated for military action in areas where the threat of biological warfare exists.

Recombinant Vaccinia Virus

Vaccinia virus is the prototype of the genus *Orthopoxvirus*.[45] It is a double-stranded DNA virus that has a broad host range under experimental conditions and is rarely isolated from animals outside the laboratory.* Many strains of vaccinia virus exist with various levels of virulence in humans and animals. Some examples include the Temple of Heaven and Copenhagen vaccinia strains, which are highly pathogenic in animals, and the NYCBOH strain, from which the Wyeth vaccine was derived, which has relatively low pathogenicity in animals and humans.[49]

Vaccinia virus can be engineered genetically to contain and express foreign DNA without impairing the ability of the virus to replicate. Such foreign DNA can encode protein antigens that induce protection against one or more infectious agents. These recombinant vaccinia viruses created from several different strains have been engineered to express the immunizing antigens of many viruses, bacteria, parasites, and tumors of veterinary and medical importance.† In the United States, recombinant viruses have been made from the NYCBOH strain or a mouse neuroadapted derivative, the WR strain. Some recombinant viruses have been made from the Copenhagen and Lister vaccinia strains, which are more pathogenic in animals than the NYCBOH strain. More recently, studies using recombinant vaccinia to vaccinate against prostate cancer, malaria, tuberculosis, and HIV have used the Ankara strain.[5,64,101] Animal studies generally suggest that recombinant viruses may be no more pathogenic than the parent strain of vaccinia virus. However, no consistently reliable laboratory marker or animal test has been able to predict the attenuation of vaccinia virus or a particular recombinant virus for humans.[136] Laboratory-acquired infections with vaccinia or recombinant viruses have been reported[75,99,117]; however, no surveillance system exists to monitor laboratory workers, thus the risk for acquiring infection in persons who handle virus cultures or contaminated materials is not known.

With the initiation of human and veterinary trials using recombinant vaccines, physicians, nurses, veterinarians, and other personnel may be susceptible to both vaccinia and recombinant agents. This exposure could occur from direct contact with the recombinant virus or contaminated dressings, but the risk for transmission is unknown. To date, no reports of transmission to health care personnel from vaccine recipients have been published. When appropriate infection control precautions are observed, health care workers exposed to smaller volumes and lower titers of virus may be at less risk for acquiring infection in contrast to their laboratory

*References 9, 32, 43, 46, 53, 137.
†References 32, 51, 55, 62, 80, 119, 120, 134.

counterparts.[54,133] However, because the risk for transmission exists in such persons, the ACIP suggests that personnel with direct exposure to volunteers in clinical studies be considered for vaccination and observe appropriate biosafety guidelines and infection control procedures.[54,127,133]

Camelpox

Camelpox virus is an orthopoxvirus that is genetically the closest known virus to variola virus (smallpox virus).[42] Its disease is restricted to camels, and it is enzootic in all regions (except Australia) where camel breeding is practiced. The illness in camels is severe, with smallpox-like lesions. Bera and associates[7] noted three human cases in animal handlers in India. The illness in all three was mild and limited to a few lesions on the hands.

Orf Virus

Orf virus is a member of the genus *Parapoxvirus* (see Table 58-1 in Chapter 58). Orf disease, also called *ecthyma contagiosum*,[45] is an occupationally acquired disease, with most cases occurring in adults.[53,83] The reservoir hosts of orf virus are sheep and goats, and the virus has worldwide distribution. Human disease is characterized by single or multiple lesions that last approximately 35 to 40 days, progress through six stages, and most often are located on the hands.[53,83] The stages include maculopapular, 1 to 7 days; target, 7 to 14 days; acute, 14 to 21 days; regenerative, 21 to 28 days; papillomatous, 28 to 35 days; and regressive, 35 to 40 or more days. Patients may have low-grade fever, but regional lymphadenitis is an uncommon finding. However, two patients with a widespread papulovesicular eruption, fever, malaise, and lymphadenopathy were described.[132] In addition, a giant orf granuloma developed at the site of a rope burn in a 12-year-old boy who lived on a farm.[98] These atypically proliferating giant orf lesions have occurred in both immunosuppressed and immunocompetent individuals. Complications after infection can occur, including erythema multiforme, bullous pemphigoid, swan-neck deformity of a finger, paresthesia, and autoimmune blistering disorders. Mortality among flocks of goats and sheep infected with orf virus can be very high, which could be economically damaging.[60]

The CDC reported four unrelated cases of cutaneous, self-resolving orf virus infections in people either exposed to sheep or goats with oral lesions or who had been vaccinated recently with live orf virus vaccine. These cases occurred in New York, Illinois, California, and Tennessee, and patients' ages ranged from 11 to 51 years.[27] Uzel and colleagues[129] reported nine cases of orf virus infection in Turkey related to feasts of sacrifice; adults involved in the preparation of the animals for consumption were found to be at risk. Four additional cases reported in the United States between 2009 and 2011 highlighted the potential for household exposures to the virus, including how food was prepared from infected animals.[29]

Until recently, diagnosis of orf virus depended on electron microscopy or serology. In 2001, Torfason and Gunadóttir[125] described the PCR method to detect orf virus that helped make identification of the virus more accessible.[96]

Orf virus has been shown to have antiviral activity against recurrent genital herpes disease in guinea pigs and hepatitis B and herpes simplex virus 1 in mice. The protection in mice happens by modulating the host innate immune system, inducing phagocytosis, natural killer cell activity, and release of interferon-α, tumor necrosis factor-α, interleukin-2, and granulocyte-macrophage colony-stimulating factor. This finding may have implications for immune therapy for patients with serious infection from these viruses.[131] Treatment with imiquimod of complicated cases in immunocompetent hosts[44] and in immunocompromised patients has been reported.[84]

Other Parapoxviruses

Human infections with pseudocowpox virus and bovine papular stomatitis virus are considered occupational diseases. Pseudocowpox infections occur on the hands of milkers, and infections with bovine papular stomatitis virus have also been reported on the hands of veterinarians and others with close contact with cows.[12,45,91] The initially red lesions of the pseudocowpox nodule are relatively painless, but they may be pruritic and will eventually become purple. They are firm, do not ulcerate, and typically last 4 to 6 weeks. In comparison, the lesions caused by bovine papular stomatitis virus are wartlike and typically last 3 to 4 weeks.

Additionally, reports on humans infected with other parapoxviruses from reindeer and seals are available.[46,47,109] One report noted that in a human infection with sealpox virus, the person had orflike lesions that resolved after biopsy specimens were obtained.[31]

Yatapoxviruses

Tanapox virus, yaba-like disease virus (YLDV), and yaba monkey tumor virus (YMTV) are three viruses found in monkeys that can cause human infection.[35,40,41,45,70] DNA maps of tanapox virus and YLDV are extremely similar, indicating they may be the same. Tanapox in humans first was observed along the Tana River in Kenya in 1957, and outbreaks in Africa, including the DRC, have involved both children and adults.[45,70]

The illness starts with fever, headache, backache, and mild prostration and skin lesions occur 2 to 4 days after onset. Individual lesions start as an itchy path, followed by the development of a pocklike lesion. At 7 days, lesions are approximately 10 mm in diameter with surrounding erythema. Lymphadenitis is both local and regional. The lesions ulcerate during the second week of illness and last approximately 6 weeks. Most patients have a single lesion, but some have 2 to 10 lesions. The prognosis usually is good, although secondary bacterial infection can occur.

Two cases of tanapox were reported in the United States. The first case was a 51-year-old man with papular lesions with general malaise after visiting Tanzania and being exposed to a cat.[123] A second case occurred in a 21-year-old female student from New Hampshire, who developed fever, headaches, malaise, and several papules after being exposed to chimpanzees in the DRC.[38] The

symptoms of both patients were diagnosed using PCR techniques and resolved spontaneously. As international travel increases, more case reports of such poxvirus illnesses may surface. PCR techniques to diagnose such infections quickly have been developed,[38,123,138] and these methods will assist in rapid diagnosis of poxvirus illnesses that may be confused with more serious illnesses such as smallpox and monkeypox. Of interest, tanapox virus has been recently been studied in human cancer cell lines in hope of developing an oncolytic viral vaccine to be used therapeutically in a variety of human cancers with minimal side effects.[85]

YMTV was isolated from tumors in monkeys in Nigeria, and animal handlers in primate centers in the United States have become ill as a result of this virus. Human infections have not been identified in the field in Africa. YMTV produces epidermal histiocytomas, tumor-like masses of histiocytic polygonal mononuclear cell infiltrates that may advance to suppurative inflammation.[35]

Molluscum Contagiosum Virus

In contrast to the other zoonotic poxviruses discussed in this chapter, *molluscum contagiosum* virus is a human virus that is a common cause of human skin lesions[45] (see Chapter 60B and Table 58-1 in Chapter 58). The virus has not been grown in cell culture as yet, but has been extracted from human lesions, and it does not cause infection in experimental animals. Analysis of viral DNA from lesions in geographically different patients indicates existence of two major subtypes and a third, rare subtype. The clinical aspects of molluscum contagiosum virus infection are presented in Chapter 60B.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Because all but two viruses presented in this chapter are zoonotic agents, careful attention must be given to geographic location and animal exposure. All diseases described here are characterized by local lesions, which easily can be collected for direct identification. All poxviruses can be identified by examination of material from lesions by electron microscopy and by PCR. All viruses except molluscum contagiosum virus grow in one or more tissue culture systems, the chorioallantoic membrane of embryonated eggs, or both. Unusual agents should be referred to specific reference laboratories for species identification.

CHAPTER 164

MIMIVIRUSES

Ramya Ramraj • Gail J. Harrison

In 1992, while investigating the source of an outbreak of community-acquired pneumonia in northern England, investigators discovered a bizarre microorganism.[10,11] The microorganism, resembling a small gram-positive coccus, was found inside a free-living ameba in a water cooling tower. Researchers initially thought it was a bacterium, but subsequent analysis demonstrated a double-stranded DNA virus. Originally named mimivirus because it resembled bacteria in Gram-stained smears, it now is designated officially as a quasi-autonomous virus, *Acanthamoeba polyphaga mimivirus.* There is a proposed new order, Megaviridae, defining a new fourth domain of life, under consideration, which may include mimivirus in the future.[4,5,12]

STRUCTURE AND PROPERTIES

A. polyphaga mimivirus is a giant, double-stranded, icosahedral DNA virus.[26] With a diameter of approximately 650 nm, mimivirus is the largest virus known to date. Mimivirus morphologically resembles nucleocytoplasmic large DNA viruses (NCLDVs), such as the iridovirus, asfarvirus, and phycodnavirus.[7,23] However, evolutionary dissimilarities define a new family, the Mimiviridae.[10] The mimivirus comprises a central dense core that is surrounded by two lipid membrane layers inside a capsid protein shell covered by fibrils. The 1.2-Mb genome sequence[15,18,21] is complex and possesses genes that are shared by the NCLDV families as well as several that have not been identified previously in viruses. The origins and the various processes[1] involved in shaping gene content of the mimivirus are not entirely clear at this time.[10,15]

The virus can survive on inanimate surfaces for at least 30 days, is resistant to alcohol-based biocidal agents, but is inactivated by free chlorine and glutaraldeyde.[3,7]

VIRAL REPLICATION

In *A. polyphaga*, the replication cycle of the mimivirus starts with entry of the virus by phagocytosis, followed by a 4-hour eclipse phase inside the nucleus,[10] and then the formation of the "virus factory" in the cytoplasmic space,[22] ending with cell lysis and virus release 24 hours after infection (Fig. 164-1). The virus factory,[16] where virus replication and assembly occur, is the major site of production of mimivirus DNA and induces profound alteration of the infected cell structure, such as by recruitment of organelles and organization of cellular compartments. Very specific mechanisms and complex interactions between viral and cellular factors that are not entirely clear at this time must be involved to build this remarkably large and efficient virus factory, which can generate this sophisticated microorganism rapidly.[22]

ANIMAL SUSCEPTIBILITY

An experimental model of infection[8] was developed to establish a possible role of mimivirus as a human pathogen. Autopsy specimens of laboratory mice that were inoculated intracardially with infecting units of mimivirus revealed histopathologic evidence of pneumonia, and mimiviruses were reisolated from samples from the lung. Inoculation of human macrophages with mimiviruses showed evidence of infection, although no evidence of a lytic cycle was observed.[19] Efforts to induce infection in other cell lines were futile, and the target cell in mice remains to be identified.

MIMIVIRUS INFECTION IN HUMANS

In December 2004, a laboratory technician in France[20] developed subacute pneumonia with dry cough, fever, and chest pain. This technician was in charge of performing mimivirus serologic testing and Western blot analysis and thus had handled relatively large amounts of mimivirus antigens. Radiographic examination of his chest revealed bilateral basilar infiltrates (Fig. 164-2). The illness did not respond to amoxicillin-clavulanate treatment prescribed on day 15 after the onset of symptoms, but after an additional 2 weeks, the illness resolved, and the technician made a full recovery. Serum samples screened against pneumonia agents showed seroconversion (<1:50 to 1:3200) only for mimivirus, which was confirmed by testing with two-dimensional Western blotting against 23 identified proteins of mimivirus.

Prevalence of Antibodies to Mimivirus in Patients with Pneumonia

Three early studies investigated the prevalence of antibodies to mimivirus in specific human populations.[19] The first study tested serum samples obtained from 376 Canadian patients with community-acquired pneumonia and from 511 healthy subjects. A total of 9.66 percent of patients with pneumonia had antibodies to mimivirus,

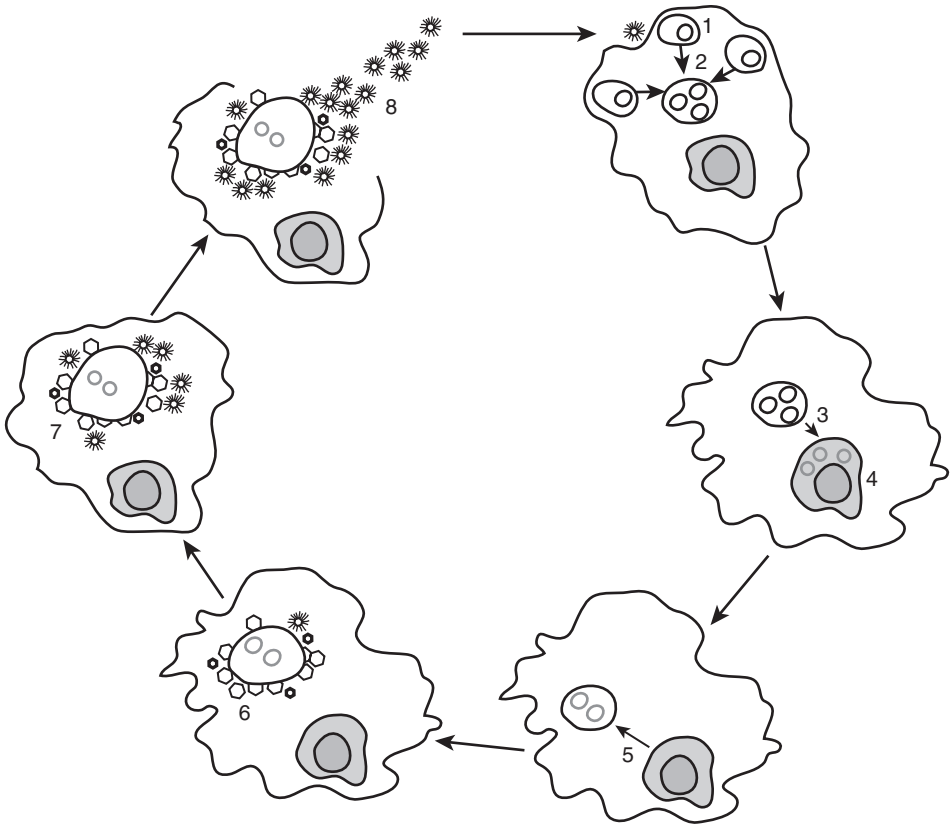

FIGURE 164-1 ■ Schematic representation of the *Acanthamoeba polyphaga mimivirus* replication cycle. *1,* Mimivirus entry through a phagocytic vacuole. *2,* Fusion of phagocytic vacuoles and delivery of mimivirus genetic material into the cell cytoplasm *(3). 3,* Mimivirus DNA entry into the host nucleus, where the first round of DNA replication could begin *(4). 5,* At 3 hours after infection, mimivirus DNA came from the host nucleus to form the virus factory (VF) replication center. *6,* At 5 hours after infection, the VF size showed a 50 percent increase, and viral proteins began to be detected; proviral capsid assembly and viral capsids budding from the VF central core could be observed. *7,* Empty or DNA-filled capsids accumulated near the central core, resulting in a growing VF with viral particles free in the cytoplasm. *8,* Complete viral capsids surrounded by fibrils may be released through cell lysis. (From Suzan-Monti M, La Scola B, Barrassi L, et al. Ultrastructural characterization of the giant volcano-like virus factory of *Acanthamoeba polyphaga Mimivirus. PLoS One* 2007;**2**:e328.)

compared with 2.3 percent of control subjects.[14] Patients with pneumonia who had antibodies to mimivirus were more likely to be hospitalized from a nursing home and to be rehospitalized after discharge.[13] The second study included 26 patients from Marseille, France, who acquired pneumonia while in an intensive care unit and 50 control serum samples (from blood donors). Antibodies to mimivirus were detected in samples obtained from 5 patients but in none of the control samples.[13] The third serosurvey involved 157 patients in intensive care units who had pneumonia. Serum specimens obtained from these patients were tested against a panel of antigens from "conventional" pneumonia agents as well as ameba-associated microorganisms, including mimivirus.[2] Evidence of infection with conventional pathogens was found in 28 cases and with ameba-associated pathogens in 18 cases. In the group infected by ameba-associated pathogens, more patients had seroconversion to mimivirus than to any other pathogen (5 cases), and seroconversion was more common among patients with ventilator-associated pneumonia than among those with community-acquired pneumonia (31.6% and 10.5% of patients, respectively). Additional serologic studies have shown an association of mimivirus seropositivity and increased duration of mechanical ventilation and prolonged stay in the intensive care unit in adult patients.[24] However, studies that have employed molecular detection techniques of reverse transcription polymerase chain reaction (RT-PCR) have not detected mimivirus DNA in respiratory secretions of hospitalized adult and pediatric patients with pneumonia.[6,9,24,25] Taken together, these studies reveal a significant rate of seroconversion and seropositivity in hospitalized patients with either community-acquired pneumonia or hospital-acquired pneumonia, but direct detection of the pathogen in clinical respiratory secretions has not been confirmed.[19]

DIAGNOSTIC METHODS

Diagnostic strategies include collection of bronchoalveolar lavage (BAL) fluid and serologic samples. Serologic testing includes immunofluorescence assay of samples of acute-phase and convalescent-phase serum for antibodies to proteins specific for mimivirus (Becton Dickinson, Rutherford, NJ).[2] However, one study employing

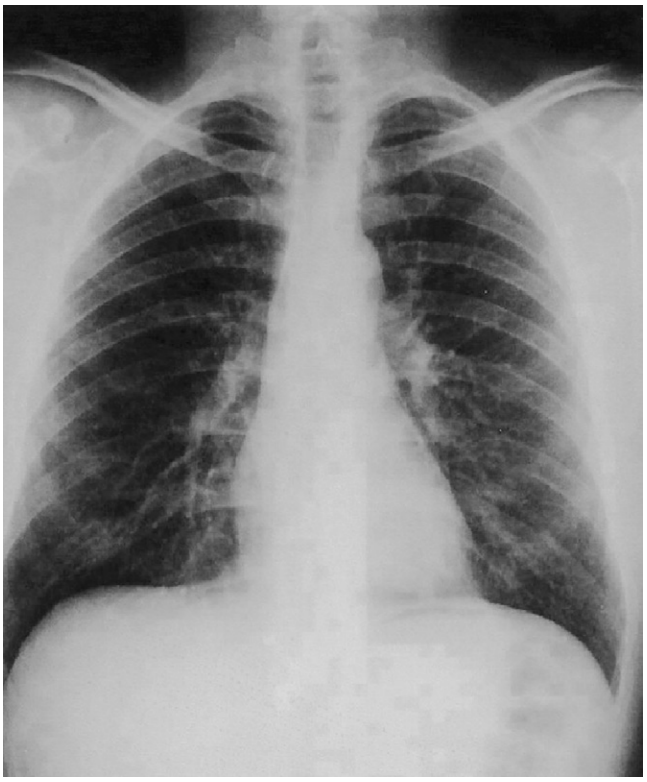

FIGURE 164-2 ■ Chest radiograph of a laboratory technician who was infected with mimivirus, with bilateral basilar infiltrates evident. (From Raoult D, La Scola B, Birtles R, et al. The discovery and characterization of Mimivirus, the largest known virus and putative pneumonia agent. *Clin Infect Dis* 2007;**45**:95–102.)

immunoproteomics showed cross reaction between mimivirus and *Francisella tularensis*, suggesting caution in interpretation of results when only serologic methods are employed to diagnose mimivirus infection or to determine associations of mimivirus and pneumonia.[17] Mimivirus also can be cultivated by co-culture with ameba. It also can be detected in DNA extracted (QIAamp tissue kit, Qiagen, Hilden, Germany) from BAL samples amplified by PCR assay.[2] However, real-time PCR methods have failed to consistently detect mimivirus in clinical respiratory secretions obtained from patients with pneumonia. The strongest evidence of infection includes a combination of positive BAL culture, positive PCR assays, and fourfold increase in antibody titer between acute-phase and convalescent-phase serum samples or significant seroconversion for mimivirus.[2]

MIMIVIRUS AS AN EMERGING PATHOGEN

Evidence indicates that mimivirus is a new human pathogen that causes pneumonia.[3] However, mimivirus does not replicate efficiently in co-culture with any of the mammalian cells tested to date, and serologic cross reactions among pathogens are observed commonly. Isolation of the virus or DNA detection by RT-PCR from respiratory secretions of patients with pneumonia has not confirmed the presence of the pathogen directly in clinical samples.[13] Mimivirus infection in hospitalized children with pneumonia has not been confirmed, and seroprevalence data in children have not been published.

RNA VIRUSES

SUBSECTION 1
PICORNAVIRIDAE

CHAPTER 165

Enteroviruses, Parechoviruses, and Saffold Viruses

James D. Cherry • Paul Krogstad

Enteroviruses (EVs) and parechoviruses (PeVs) make up two genera of the family *Picornaviridae*. Saffold viruses (SAFVs) are genetically related to Theiler marine encephalomyelitis virus.[1114] They are classified as a new species in the genus *Cardiovirus*. These small RNA viruses are responsible for frequent and often significant human illnesses with protean manifestations.* To bring order to the growing list of poliovirus-like agents, coxsackieviruses, echoviruses, and polioviruses first were categorized together and named in 1957 by a committee sponsored by the National Foundation for Infantile Paralysis.[711] These viruses were grouped together because of similarities in their biophysical properties, shared features in their epidemiology and pathogenesis, and the many disease syndromes they caused. The human alimentary tract was thought to be the natural habitat of these agents, and the term *enterovirus* was coined. Newer agents later assigned to the genus *Enterovirus* were simply numbered sequentially, and more than 110 distinct human EV (HEV) types now are recognized. The two viruses originally classified as echoviruses 22 and 23 were reclassified into a new genus *(Parechovirus)* within the *Picornaviridae* family because of features of their structure and replication that distinguish them from the EVs.[954]

HISTORY

Poliomyelitis, the first enteroviral disease to be recognized and the most important one, has a long history.[812] The earliest record is an Egyptian stele of the 18th dynasty (1403 BCE to 1365 CE) that shows a young man with a withered, shortened leg, the characteristic deformity of paralytic poliomyelitis.[461,704] Michael Underwood,[1015] a London pediatrician, published the first medical description in 1789 in *A Treatise on Diseases of Children*. During the 19th century, many reports appeared in Europe and the United States describing small clusters of cases of "infantile paralysis." The authors were puzzled about the nature of the affliction; not until the 1860s and 1870s was the spinal cord firmly established as the seat of the pathologic process. The contagious nature of poliomyelitis was not appreciated until the late 19th century. Medin, a Swedish pediatrician, was the first to describe the epidemic nature of poliomyelitis (1890), and his pupil Wickman worked out the basic principles of the epidemiology.[1066]

The virus was isolated first in monkeys by Landsteiner and Popper[613] in 1908. The availability of a laboratory animal assay system opened many avenues of research that in the ensuing decades led to the demonstration that an unrecognized intestinal infection was the usual manifestation and the paralytic disease was a relatively uncommon event.

Coxsackieviruses and echoviruses have had a shorter history. Epidemic pleurodynia was described clinically in 1735 by Hannaeus[419] more than 200 years before the coxsackieviral origin of this disease was discovered. In 1948, Dalldorf and Sickles[254] first reported the isolation of a coxsackievirus after inoculation of suckling mice.

In 1949, Enders and associates[302] described the growth of poliovirus 2 in tissue culture, and their techniques paved the way for recovery of a large number of other cytopathic viruses. Most of these "new" viruses failed to produce illness in laboratory animals. Because the relationships of many of these newly recovered agents with human disease were unknown, these agents were called *orphan viruses*.[703] Later, several agents were grouped together and were called *e*nteric *c*ytopathogenic *h*uman *o*rphan viruses, or echoviruses. More recently, using molecular detection methods, SAFVs were identified in human infections.[531,1114]

*Many enterovirus strains have been isolated that do not conform to these categories, leading to the revised classification scheme shown in Table 165-2.

†New types, beginning with type 68, were initially assigned enterovirus type numbers instead of coxsackievirus or echovirus numbers. Types 68 through 71 were identified before the strategy for taxonomy was changed, as described in the text.

‡Coxsackievirus A23 was found to be the same as echovirus 9.

§Echovirus 10 was reclassified as a reovirus; echoviruses 22 and 23 were made the first members of the parechovirus genus within the picornavirus family and echovirus 28 was reclassified as a rhinovirus.

+, Present; –, absent; ±, variably present.

Inactivated and live-attenuated poliovirus vaccines became available in the late 1950s and early 1960s, and the most notable advance since the late 1980s has been a dramatic reduction in worldwide poliomyelitis as a result of the global immunization initiative.[227,483,802,988] The last case of confirmed paralytic poliomyelitis in the Western Hemisphere caused by a wild-type virus strain occurred in 1991.[868]

THE VIRUSES

Classification

EVs, PeVs, and SAFVs are RNA viruses belonging to the family *Picornaviridae* (*pico*, "small").* These viruses are grouped together because they share certain physical, biochemical, and molecular properties. In electron micrographs, the viruses are seen as 30-nm particles that consist of naked (nonenveloped) protein capsids, constituting approximately 70 to 75 percent of the mass of particles that contain the genomic RNA.

The original classification of HEVs is shown in Table 165-1. The EVs originally were distributed into four groups based on their different effects in tissue culture and pattern of disease in experimentally infected animals: polioviruses (causal agents of poliomyelitis in humans and nonhuman primates), coxsackieviruses A (associated with herpangina, human central nervous system [CNS] disease, and flaccid paralysis in suckling mice), coxsackieviruses B (human CNS and cardiac disease, spastic paralysis in mice), and the echoviruses (nonpathogenic in mice and not linked to human disease at first).

Although this scheme was useful initially, many strains were isolated subsequently that do not conform to such rigid specificities. For example, several coxsackievirus A strains replicate and have a cytopathic effect in monkey kidney tissue cultures, and some echovirus strains cause paralysis in mice. For this reason, and to simplify the nomenclature, EVs subsequently were assigned sequential numbers. Following this convention, the prototype EV strains Fermon, Toluca-1, J 670/71, and BrCr (identified between 1959 and 1973) were designated EV 68 through EV 71, respectively. Additional EVs continued to be identified that could not be using antisera specific for the classic serotypes. More than 40 distinct EVs have been identified by culture and molecular detection methods, although many have not been linked to human disease.

Since the late 1990s, genetic, biologic, and molecular properties have been used to revise picornavirus taxonomy. Determining the nucleotide sequence encoding the viral VP1 capsid protein plays a major role in this approach and predictably identifies viruses originally classified by serologic means, thus leading to the term *molecular serotyping*.[787,788,833,839] This phylogenetic technique formed the basis of a reorganization of the HEVs into four alphabetically designated species (HEV-A, B, C, and D) (Table 165-2). The three human polioviruses (PV1 to 3) have been classified as members of HEV-C, in view of their close molecular relationship to other members of the species.[108]

Two of the original echoviruses (E22 and E23) have long been known to exhibit genomic and proteomic differences from the other early "enteroviruses" and were reclassified as first members of the new genus *Parechovirus* as *Parechovirus* types 1 and 2.[843,954,955] More than a dozen additional types of human PeV have now been identified. Similarly, hepatitis A virus initially was assigned the designation EV 72, but it was reclassified as the sole member of the *Hepatovirus* genus within the picornavirus family because of marked genetic and biologic distinctions from the EVs.

The *Cardiovirus* genus of the Picornaviridae has recently been augmented by identification of the SAFVs. Beginning with a strain isolated in 2007, eight genetically distinct SAFVs have been identified since 2007 and added to the *Cardiovirus* genus as members of the *theilovirus* spp.[531]

King AMQ, Adams MJ, Carstens EB, et al, editors. Virus taxonomy: classification and nomenclature of viruses: ninth report of the International Committee on Taxonomy of Viruses. San Diego: Elsevier Academic Press, 2011.
Coxsackievirus (CV) A15 has been reclassified as a strain of CVA11, and CVA18 as a strain of CVA13. Echovirus 34 has been recognized as a variant of coxsackievirus A24.

TABLE 165-3 **Cellular Receptors and Cofactors for Infection of Representative Enteroviruses**

Virus	HEV Species	Receptor	Cofactor for Infection*
Enterovirus 71	HEV-A	PSGL-1, SCARB2	
Coxsackieviruses B1-6	HEV-B	CAR	Some group B coxsackieviruses may use CD55 (DAF) or heparan for attachment
Echovirus 9	HEV-B	$\alpha_v\beta_3$ integrin (vitronectin receptor)	MAP-70
Echoviruses 1, 8	HEV-B	VLA-2 ($\alpha_2\beta_1$ integrin)	Heparan sulfate
Coxsackieviruses A13, 17, 20, 21, 24	HEV-C	ICAM-1	
Polioviruses 1-3	HEV-C	CD155(PVR)	
Enterovirus 70	HEV-D	CD55 (DAF)	

*The cofactors generally facilitate adhesion to cells, but their sole expression is insufficient to permit infection to occur.
CAR, Coxsackie and adenovirus receptor; *DAF,* decay accelerating factor; *HEV,* human enterovirus; *ICAM 1,* intercellular adhesion molecule 1; *MAP-70,* microtubule-associated protein 70; *PSGL-1,* P-selectin glycoprotein ligand 1; *Pvr,* poliovirus receptor; *SCARB2,* scavenger receptor class B member 2; *VLA-2,* a human integrin.

The application of molecular phylogenetic approaches also revealed that recombination between circulating picornaviruses is a frequent event and is likely to increase their genetic diversity of EVs, cardioviruses, and PeVs.* This propensity for recombination has played a role in more recent outbreaks of paralytic diseases involving vaccine-derived strains of poliovirus.[563]

Morphology and Replication

The genome of EVs and PeVs is a single-stranded, positive-sense RNA molecule approximately 7.4 kb in length.[834] It consists of a 5′ noncoding region followed by a single long open-reading frame, a short 3′ noncoding region, and a polyA tail. The 5′ noncoding region contains an internal ribosome entry site that recruits the translational machinery to an initiation site approximately 740 nucleotides downstream from the 5′ terminus of the viral RNA . The 3′ noncoding region folds into highly conserved secondary and tertiary structures that are thought to play a role in the initiation of the replication of the viral genome. This genome is packaged into capsids that exhibit icosahedral symmetry with 20 triangular faces and 12 vertices.

Replication of EVs begins with the adsorption of virions to cell surface receptors, which, for the most part, are integrins or immunoglobulin-like proteins (Table 165-3). The virions penetrate the surface of cell and undergo conformational changes that release the viral genome, which functions as messenger RNA for the viral polyprotein.[636,927] This polypeptide contains three domains, P1 to P3, which are cleaved into three or four proteins each. The P1 region is liberated from the polyprotein by the viral 2A protein, a chymotrypsin-like protease. P1 initially is split into three proteins, VP0, VP1, and VP3, by the viral 3C protease. VP0 then is processed further into two smaller proteins, VP4 and VP2. Portions of VP1, VP2, and VP3 are exposed at the surface of the virion, whereas VP4 is entirely internal. VP1, VP2, and VP3 have no sequence homology but share the same topology.[843] Specifically, they form an eight-stranded antiparallel β-barrel that is wedge shaped and comprises two antiparallel β-sheets. The amino acid sequences in

*References 74, 160, 197, 281, 657-659, 785, 796, 942, 970.

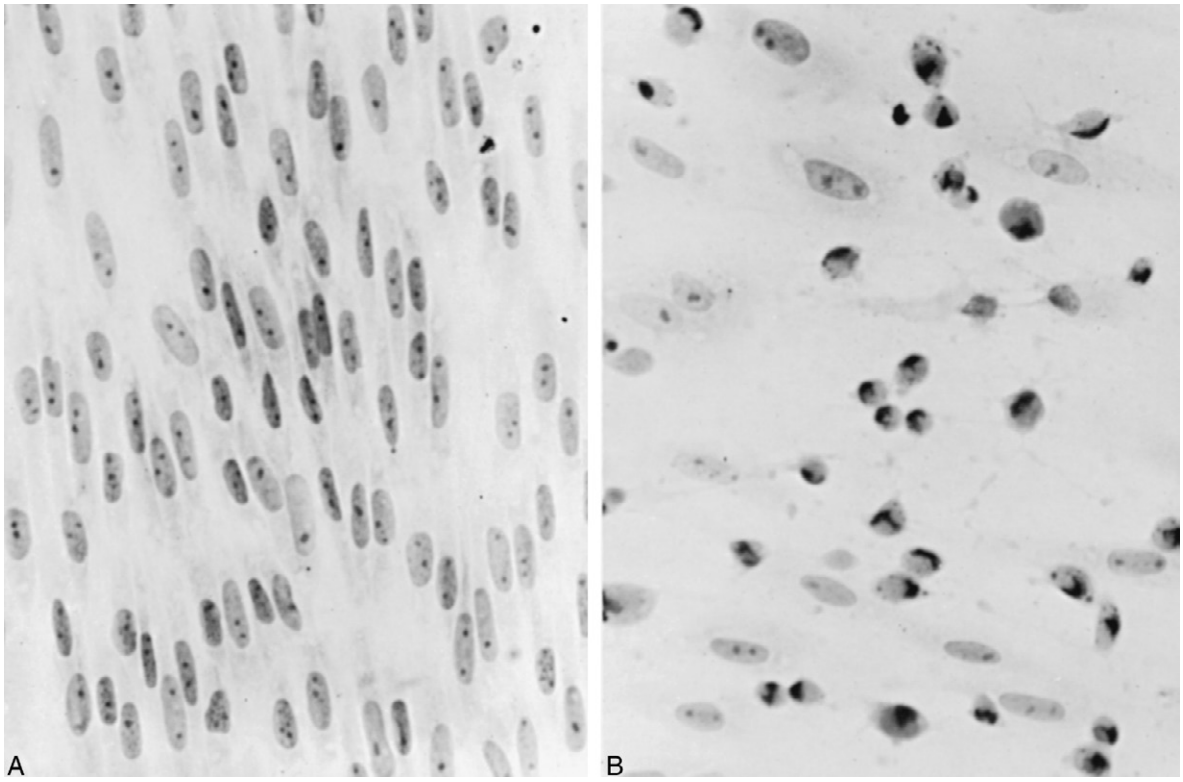

FIGURE 165-1 ■ Fetal rhesus monkey kidney tissue culture (HL-8). **A,** Uninoculated tissue culture. **B,** Echovirus 11 cytopathic effect. (From Cherry JD. Enteroviruses. In: Remington JS, Klein JO, editors. *Infectious diseases of the fetus and newborn infant.* Philadelphia, W.B. Saunders, 1976.)

the loops that connect the β-strands and the N- and C-terminal sequences that extend from the β-barrel domain of VP1, VP2, and VP3 give each EV its distinct antigenicity. The replication of EVs occurs in the cytoplasm in membrane-associated replication complexes and is completed rapidly (5 to 10 hours). Studies of polioviruses and coxsackieviruses have shown that enteroviral replication is associated with disruption of cellular protein secretion, and host-cell protein synthesis is suppressed because of cleavage of human eukaryotic translation initiation factor 4G (eIF4G) by enteroviral 2A proteases, which abrogates cap-dependent translation. The coxsackievirus 2A protein also cleaves dystrophin, a cytoskeletal protein; this activity has been hypothesized to play a role in damage to the myocardium.[43,272]

The PeVs replicate in a similar fashion.[597] Integrins ($\alpha_v\beta_3$ and perhaps $\alpha_v\beta_1$ and $\alpha_v\beta_6$) are used as receptors, and replication occurs in cytoplasmic structures.[926] However, the P1 portion of the viral polyprotein is processed into only three capsid proteins, and only one protease has been identified in the PeVs. In addition, PeV replication occurs in small, discrete foci in the cytoplasm, rather than in large accumulations of membranous vesicles like the EVs. Moreover, transcription and translation do not appear to be disrupted by the PeVs, thus perhaps explaining their relatively mild and delayed cytopathic effect when they are grown in tissue culture.[957]

The replication of the Saffold cardioviruses has not been specifically examined, but genetic similarities to Theilers murine encephalomyelitis virus (TMEV) and other murine cardioviruses suggest that they possess a single protease related to the 3C protease of other picornaviruses.[451] The SAFV genome also appears to encode a leader (L) protein at the amino terminus of the viral polyprotein. The L proteins of TMEV and encephalomyocarditis viruses are thought to modulate viral translation, innate immune responses, and cellular apoptosis.[450]

Replication Characteristics and Host Systems

EVs and PeVs are relatively stable viruses in that they retain activity for several days at room temperature and can be stored indefinitely at ordinary freezer temperatures (–20°C [–4°F]). They are inactivated quickly by heat (>56°C [132.8°]), formaldehyde, chlorination, and ultraviolet light, but they are refractory to ether, ethanol, and isopropanol.[708,711,803,878]

Enteroviral strains grow rapidly when adapted to susceptible host systems and cause cytopathologic features in 2 to 7 days. The typical tissue culture cytopathic effect is shown in Figure 165-1; characteristic pathologic findings in mice are shown in Figures 165-2 and 165-3. Final titers of virus recovered in the laboratory vary markedly among different viral strains and the host system used; typically, concentrations of 10^4 to 10^8 infectious units per milliliter of tissue culture fluid or tissue homogenate are obtained. Unadapted viral strains frequently require long periods of incubation. In both tissue culture and suckling mice, evidence of growth usually is visible. Blind passage

occasionally is necessary for the cytopathologic features to become apparent.

Although many different primary and secondary tissue culture systems support the growth of various EVs, primary rhesus monkey kidney cultures generally are accepted to have the most inclusive spectrum.[113] Other simian kidney tissue cultures, however, also have the same broad spectrum. Tissue cultures of human origin have a more limited spectrum, but several echovirus types have shown more consistent primary isolation in human than in monkey kidney culture. A satisfactory system for the primary recovery of EVs from clinical specimens would include primary rhesus, cynomolgus, or African green monkey kidney; a diploid, human embryonic lung fibroblast cell strain; rhabdomyosarcoma cell line tissue cultures; and intraperitoneal and intracerebral inoculation of suckling mice younger than 24 hours.*

Antigenic Characteristics

Although some minor cross reactions exist among several coxsackievirus and echovirus types, common group antigens of diagnostic importance have not been defined well.[704,706,707,711,801] Heat treatment of virions and the use of synthetic peptides have produced antigens with broad enteroviral reactivity.[899,990] These antigens have been used in enzyme-linked immunosorbent assay (ELISA) and complement fixation tests to determine immunoglobulin (Ig)G and IgM enteroviral antibodies and for antigen detection. In one study, Terletskaia-Ladwig and colleagues[990] reported the identification of patients infected with EVs by the use of an IgM enzyme immunoassay (EIA). This test used heat-treated coxsackievirus B5 and echovirus 9 as antigens, and it identified patients infected with echoviruses 4, 11, and 30. The sensitivity of the test was 35 percent. In another study involving heat-treated virus or synthetic peptides, the respective sensitivities were 67 and 62 percent.[899] However, both tests lacked specificity. Intratypic strain differences are common findings, and some strains (prime strains) are neutralized poorly by antisera to prototype viruses. In animals, however, these prime strains induce antibodies that neutralize the specific prototype viruses.

The identification of polioviral, coxsackieviral, and echoviral types by neutralization in suckling mice or tissue culture with antiserum pools is relatively well defined. Neutralization is induced by the epitopes on structural proteins VP1, VP2, and VP3; in particular, several epitopes are clustered on VP1. Prime strains do cause diagnostic difficulty because frequently they are not neutralized by the reference antisera, a particular problem with echoviruses 4, 9, and 11 and EV 71. If these types are suspected, in some instances this problem can be overcome by using antisera in less diluted concentrations or antisera prepared against several different strains of problem viruses. Kubo and associates[600] were able to type enteroviral isolates not identified through neutralization by nucleotide sequence analysis of the VP4 gene. They specifically identified prime strains of echovirus 18 and EV 71. Sequence analysis of the VP1 gene also is useful for typing enteroviral prime strains not identified by neutralization.[775]

Host Range

Humans are the only natural hosts of polioviruses, coxsackieviruses, and echoviruses.* However, EVs have been recovered in nature from sewage, flies, swine, dogs, a calf, a budgerigar, a fox, mussels, monkeys, and oysters.[182] In addition, serologic evidence of infection with EVs similar to human strains has been noted in chimpanzees, cattle, rabbits, a fox, a chipmunk, and a marmot.[182] A variety of EVs that are distinct from the human EVs have been isolated from nonhuman primates.[784] Contamination of shellfish also is interesting because in addition to their possible role in human infection, shellfish offer a source of enteroviral storage during periods of cold weather.[182] Contaminated food is another possible source of human infection.[182]

EPIDEMIOLOGY

Transmission

The spread of HEVs, PeVs, and also presumably SAVFs, is from person to person by the fecal-oral and possibly the oral-oral (respiratory spread) route. Swimming and wading pools may serve as a means of spread of EVs during the summer.[559] Oral-oral transmission by way of the contaminated hands of health care personnel and transmission by fomites were documented in a chronic care pediatric ward.[520] EVs have been recovered from trapped flies, and such carriage probably contributes to the spread of human infection, particularly in lower socioeconomic populations with poor sanitation facilities.[182] Between 1972 and 2004, Sinclair and colleagues[944] noted 13 outbreaks of EV disease related to swimming in lakes, pools, or the ocean. One noteworthy point source outbreak occurred in a group of travelers to Mexico who swam in contaminated seawater.[944]

Children are the main susceptible cohort; they are immunologically susceptible, and their unhygienic habits facilitate the spread of infection. Spread is from child to child (from feces to skin to mouth) and then within family groups. Recovery of EVs is related inversely to age, but the prevalence of specific antibodies is related directly to age. The incidence of infection and the prevalence of antibodies do not differ between boys and girls.

Geographic Distribution and Season

EVs, PeVs, and SAFVs have worldwide distribution.[182,330,332,347,365,1114] Neutralizing antibodies for specific viral types have been noted in serologic surveys throughout the world, and most strains have been recovered in global isolation studies. In any given area, frequent fluctuations occur in predominant types. Epidemics probably depend on newly susceptible individuals in the population rather than on reinfection. Epidemics may be

*References 64, 427, 440, 707, 709, 876.

*References 253, 365, 569, 703, 761, 923, 1060, 1062.

localized and sporadic, and they may vary in origin from place to place in the same year. Pandemic waves of infection also occur.

In temperate climates, enteroviral infections occur primarily in the summer and fall, but in the tropics, they are prevalent all year.[182,365,706] A basic concept in understanding the epidemiology of these illnesses concerns the far greater frequency of unrecognized infection than clinical disease, as illustrated by poliomyelitis, which remained an epidemiologic mystery until researchers appreciated that unrecognized infections were the main source of contagion. Serologic surveys were instrumental in elucidating the problem; in populations living in conditions of poor sanitation and hygiene, epidemics did not occur, but wide dissemination of polioviruses was confirmed by demonstrating the presence of specific antibodies to all three types in almost 100 percent of children by the time they reached 5 years of age.

Epidemics of poliomyelitis first began to appear in Europe and the United States during the latter part of the 19th century; they continued with increasing frequency in economically advanced countries until the introduction of effective vaccines in the 1950s and 1960s.[94,217,461,812] The evolution from endemic to epidemic follows a characteristic pattern beginning with collections of a few cases, then endemic rates that are higher than usual, followed by severe epidemics with high attack rates. The age group attacked in endemic areas and in early epidemics is the youngest; more than 90 percent of paralytic cases begin in children younger than 5 years of age. Once this pattern of epidemicity begins, it is irreversible unless preventive vaccination is performed.

As epidemics recur over a period of years, a shift in age incidence occurs whereby relatively fewer cases are seen in the youngest children; the peak often is in the 5- to 14-year-old group, and increasing percentages of cases develop in young adults. These changes are correlated with socioeconomic factors and improved standards of hygiene—when children are protected from immunizing infections in the first few years of life, the pool of susceptible persons builds up, and introduction of a virulent strain often is followed by an epidemic.[461] The extensive use of vaccines since the late 1950s resulted in the elimination of paralytic poliomyelitis from large geographic areas, but the disease remains endemic in various parts of the world. Although seasonal periodicity is distinct in temperate climates, some viral activity does take place during the winter months.[182] Infection and the acquisition of postinfection immunity occur with greater intensity and at earlier ages in crowded, economically deprived populations with less efficient sanitation.

Molecular techniques have allowed researchers to study the genotypes of specific viral types in populations over the course of time.[278,498,644,741] For example, Mulders and colleagues[741] studied the molecular epidemiology of wild poliovirus 1 in Europe, the Middle East, and the Indian subcontinent. These investigators found that four major genotypes were circulating. Two genotypes were found predominantly in eastern Europe, a third genotype was circulating mainly in Egypt, and the fourth genotype was dispersed widely. All four genotypes were present in Pakistan.

Prevalence of Different Types

The epidemiologic behavior of coxsackieviruses and echoviruses parallels that of polioviruses, in which unrecognized infections far outnumber infections with distinctive symptoms. The agents are disseminated widely throughout the world, and outbreaks caused by one or another type occur regularly. These outbreaks tend to be localized, with different agents prevalent in different years. In the late 1950s, however, echovirus 9 had a far wider circulation; it swept through a large part of the world and infected not only children but also young adults.

Coxsackievirus A16 viral infection with hand-foot-and-mouth disease first was noted in Toronto and New Zealand in 1957.[188] Subsequently, illness caused by this virus was noted throughout the world. Antibody studies and viral isolation studies in 1957 to 1963 in California and Wisconsin indicated that coxsackievirus A16 was a newly circulating virus.[186,188] Since the 1960s, coxsackievirus A16 outbreaks of hand-foot-and-mouth disease continued to occur in the United States. However, since 1968, this virus has not been one of the five most prevalent yearly isolates (Table 165-4).

EV 71 was first isolated in California from patients with aseptic meningitis from 1969 to 1972.[795,917] Subsequently, this virus has been noted in the United States in association with aseptic meningitis and occasionally with encephalitis. The clinical manifestations of EV 71 changed, and the chronology of this is presented by Oii and colleagues.[795] In addition to aseptic meningitis, hand-foot-and-mouth disease and a broad range of encephalitis presentations (e.g., paralytic disease and brain stem encephalitis) occurred. In Japan, in 1973,1977, and 1978, 1031 cases occurred; most patients had hand-foot-and-mouth disease. Since 1997, severe hand-foot-and-mouth disease with paralysis, cardiorespiratory dysfunction, and brain stem encephalitis has had epidemic occurrence in Malaysia, Taiwan, Singapore, Brunei, Japan, China, and other Asian-Pacific countries.

Although severe EV 71 disease has occurred occasionally in North America and Western Europe, epidemics similar to those occurring in the Asian-Pacific region have not been noted.[44,717,795] There are three genotypes of EV 71: A, B, and C. B and C have subtypes B 1 to 5, and C 1 to 5. However, there does not appear to be a clear association with specific sub-types and the occurrence of more severe disease. Chang and colleagues[162] found that the human leukocyte antigen (HLA)-A33 phenotype was associated with EV 71 infections. This HLA-A33 phenotype is common in Asian populations but is rare in white populations. This suggests a possible reason for the difference in epidemic occurrence in the Asian-Pacific region and the United States and Western Europe.

After a long absence, a particular agent may return and circulate among susceptible persons of different ages who have been born since the last epidemic. Other agents remain endemic in a given area and surface as sporadic cases and occasionally in small outbreaks. Multiple types frequently are active at the same time, although one agent commonly is predominant in a given locality.

TABLE 165-4 **Predominant Types of Nonpolio Enteroviral Isolations in the United States: 1961 to 2008***

	Five Most Common Viral Types Per Year

*The majority of patients from whom viruses were isolated had neurologic illnesses.

†Third and fourth place tie.

Listed in Table 165-4 are the five most prevalent nonpolio enteroviral isolations per year in the United States from 1961 through 2008* (also, Personal communication, JP Alexander, LJ Anderson, Respiratory and Enterovirus Branch, Centers for Disease Control and Prevention [CDC], 1990; H. Gary, Respiratory and Enteric Viruses Branch, CDC, 1996; A. LaMonte-Fowlkes, Epidemiology Branch, Division of Viral Diseases, National Center for Immunization and Respiratory Diseases, CDC).

Most patients from whom viruses were isolated had neurologic illnesses. Other EVs also possibly were prevalent but did not cause clinical disease sufficiently severe enough to induce physicians to submit specimens for study. In addition, probably many coxsackievirus A infections, even in epidemic situations, have gone undiagnosed because inoculation of suckling mice was not performed. Although more than 62 nonpolio EV types and 4 PeV types have been identified, of interest is that in the 48 years covered in Table 165-4, only 24 different virus types are noted. Khetsuriani and associates[153] at the CDC presented an extensive report on enteroviral surveillance in the United States for the period from 1970 to 2005. During this period, the most common enteroviral isolates, in order, were echoviruses 9, 11, and 30; coxsackievirus B5; and echovirus 6. During the period from 2000 to 2005, the most common isolates, in order, were echoviruses 9, 30, 18, and 13 and coxsackievirus B5. The extensive EV surveillance report (between 1970 and 2005) contained data on both serotype and genomic species designation.[153] Of 49,637 viral isolates, 58 different EV serotypes and 2 PeV serotypes were identified. Of these isolates, 94.6, 3.1, 0.3, and 0.1 percent were genomic species HEV-B, HEV-A, HEV-C, and HEV-D, respectively, and 1.9 percent were PeVs. Similar serotype and genomic species data are also available for 2006 to 2008.[150] During this period, 15 serotypes were identified, and 13 of which were genomic species HEV-B.

Similar data for the most common enteroviral isolates in Spain from 1988 to 1997 and in Belgium from 1980 to 1994 are available.[284,1005] The EV isolated most frequently in both countries was echovirus 30. In 1997 and 1998, major epidemic disease caused by EV 71 occurred in Taiwan, Malaysia, Australia, and Japan.[109,159,453,591,694]

Even though the use of live polioviral vaccine has eliminated epidemic poliomyelitis in the United States, determining the effect polio vaccine viruses has had on EV ecology has been difficult. In 1970, polioviruses accounted for only 6 percent of the total number of enteroviral isolations from patients with neurologic illnesses.[182] Although the numbers are not directly comparable, more than one third of the enteroviral isolations in 1962 from similar patients were polioviruses.[182] However, Horstmann and colleagues[463] studied specimens from sewage and from asymptomatic children during the early vaccine era and noted that the number of yearly polioviral isolations (presumably vaccine strains) was greater than the number of nonpolio EVs. The prevalence of vaccine viruses apparently did not affect the seasonal epidemiology of other EVs.

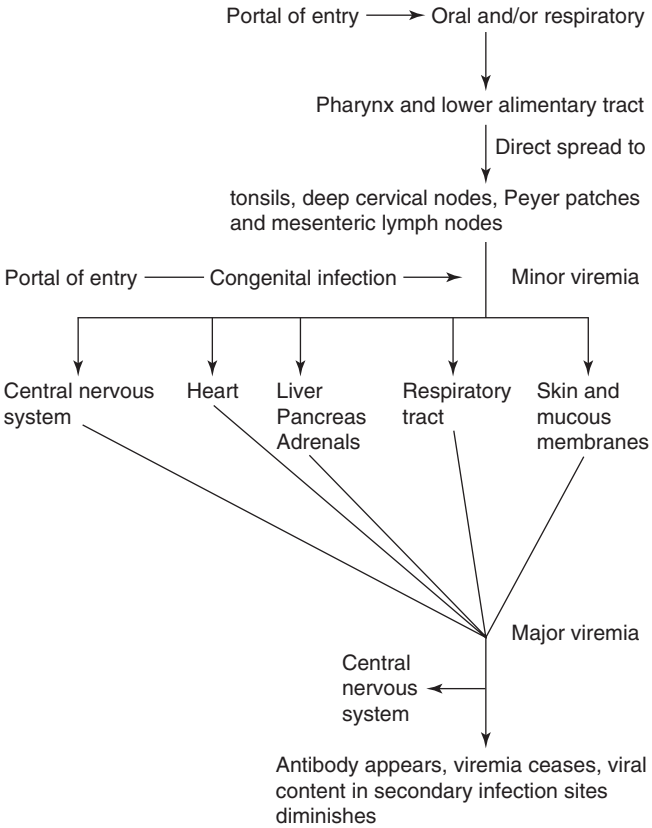

FIGURE 165-4 ■ Pathogenesis of enteroviral infections. (From Cherry JD. Enteroviruses. In: Remington JS, Klein JO, editors. *Infectious diseases of the fetus and newborn infant.* Philadelphia, W.B. Saunders, 1976.)

PATHOGENESIS AND PATHOLOGY

Events During Pathogenesis

Figure 165-4 diagrams the events in pathogenesis. After initial acquisition of virus by the oral or respiratory route, implantation occurs in the pharynx and the lower alimentary tract.* Within 1 day, the infection extends to the regional lymph nodes. On approximately the third day, minor viremia develops and results in the involvement of many secondary infection sites. In congenital infections, the infection is initiated during the minor viremia phase. Multiplication of virus in secondary infection sites coincides with the onset of clinical symptoms. Illness can vary from minor infection to fatal disease. Major viremia occurs during the period of multiplication of virus in secondary infection sites; this period usually lasts from the third to the seventh day of infection. In many echovirus and coxsackievirus infections, involvement of the CNS apparently occurs at the same time as other secondary organ involvement. Occasionally, the CNS symptoms of enteroviral infections are delayed, thus suggesting that seeding occurred later in association with the major viremic phase.

*References 94, 181, 182, 455, 707, 801, 895.

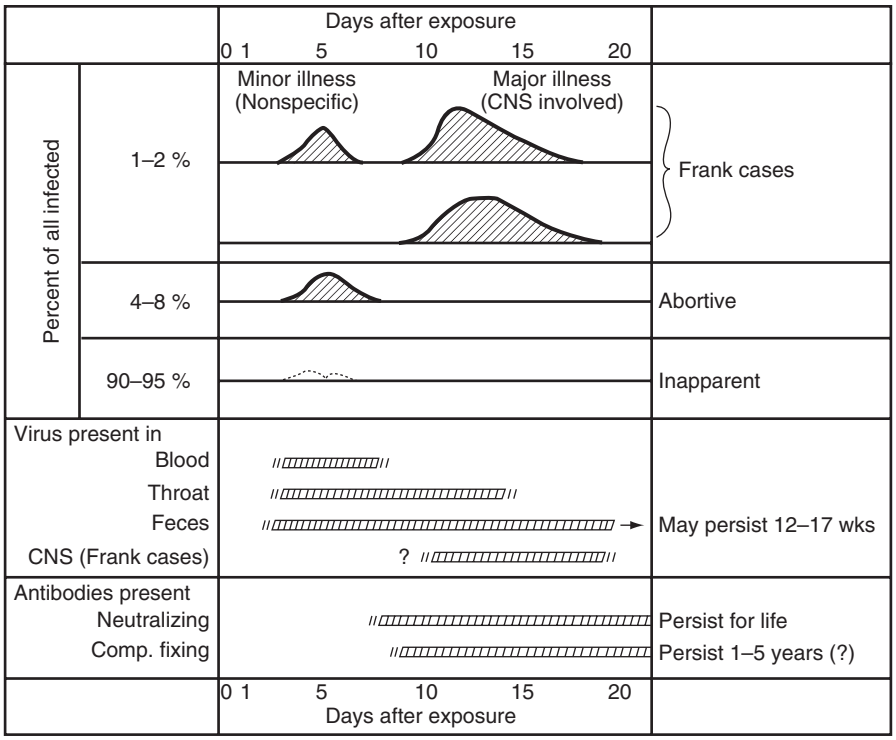

FIGURE 165-5 ■ The course of clinical and subclinical forms of poliovirus infection in relation to the presence of virus and the development of antibodies. *CNS,* Central nervous system. (From Bodian D, Horstmann DM. Poliomyelitis. In: Horsfall FL, Tamm I, editors. *Viral and rickettsial infections of man.* 4th ed. Philadelphia, J. B. Lippincott, 1965, p. 430-73.)

Cessation of viremia correlates with the appearance of serum antibody. The viral concentration in secondary infection sites begins to diminish on approximately the seventh day. However, infection continues in the lower intestinal tract for prolonged periods.

In Figure 165-5, clinical and subclinical events in polioviral infections are presented. By 3 to 5 days after exposure, virus can be recovered from blood, the throat, and feces. This finding may be accompanied by symptoms of the "minor illness," or the infection may be unrecognized clinically. The end of the period of viremia coincides with the appearance of antibodies and the onset of clinical signs of CNS involvement. The available evidence favors blood as the main pathway of CNS invasion in natural disease, but experimental infections in monkeys indicated that the virus can travel along the axons of peripheral nerves. Possibly, when tonsillectomy is performed on a child with an inapparent poliovirus infection, the virus enters the nerve fibers exposed during surgery and spreads to the cranial nerve nuclei in the brain, thereby resulting in bulbar paralysis.

Factors That Affect Pathogenesis

The pathogenesis and pathology of enteroviral and parechoviral infections depend on the virulence, tropism, and inoculum concentration of virus, as well as on many specific host factors. EVs obviously have marked differences in both tropism and virulence. Although some generalizations can be made with regard to tropism, marked differences occur even among strains of specific viral types. Differences in the virulence of specific enteroviral types may be the result of recombination among EVs or point mutations.[849,866,908]

Van Eden and associates[1021] studied 17 families during an outbreak of poliomyelitis caused by type 1 virus in the Netherlands. The findings suggested that HLA-related genetic factors were important in the occurrence of paralytic disease.

Enteroviral infections in the fetus and neonate generally are thought to be more severe than similar infections in older persons. This situation undoubtedly is the case with coxsackievirus B infection and probably also with coxsackievirus A and echovirus infections. Although the reasons for this increased severity are unknown, several aspects of neonatal immune mechanisms have been suggested. In addition, the similarity of coxsackievirus B infections in suckling mice to those in human neonates provided a useful animal model system. Heineberg and associates[434] compared coxsackievirus B1 infections in 24-hour-old suckling mice with similar infections in older mice. These investigators noted that adult mice produced interferon in all infected tissues, whereas suckling mice produced only small amounts of interferon in the liver. These researchers thought that the difference in outcome of coxsackievirus B1 infection in suckling and older mice could be explained by the inability of cells of the immature animals to elaborate interferon. Additional studies of abnormalities of innate immunity in neonates may enhance our understanding of the severity of enteroviral infections in newborns.[637]

Other researchers suggested that the increased susceptibility of suckling mice to severe coxsackievirus infections is related to the transplacentally acquired, increased

concentrations of adrenocortical hormones.[63,96] Kunin[603] suggested that the difference in age-specific susceptibility could be explained at the cellular level. He showed that various tissues of newborn mice bind coxsackievirus B3, whereas tissues of adult mice are virtually inactive in this regard.[602,603] The progressive loss of receptor-containing cells with increasing age may be the mechanism that accounts for less severe infections in older animals. Supporting this suggestion, Ito and colleagues[505] showed that expression of coxsackievirus and adenovirus receptor (CAR) decreases with increasing age in rats. In the past, researchers assumed that specific disease in various organs and tissues in enteroviral infections was caused by the direct cytopathic effect and tropism of a particular virus. In more recent years, however, large numbers of studies using murine model systems suggested that host immune responses contribute to the pathologic process.* These studies suggested that T-cell–mediated processes and virus-induced autoimmunity cause both acute and chronic tissue damage. In contrast, other studies suggested that the primary viral cytopathic effect is responsible for the tissue damage and that the various T-cell responses are a reaction to the damage and not its cause.[693]

Since the early 1960s, the clinical manifestations caused by several enteroviral serotypes have changed. For example, echovirus 11 infection initially was noted in association with an outbreak of upper respiratory tract infection in a daycare center in 1958.[822] Then, in the 1960s, this infection was found to be related to exanthem and aseptic meningitis.[187,194] Following this event and occurring at present is the association of echovirus 11 infection and severe sepsis-like illness with hepatitis in neonates.†

Another example relates to EV 71 infections. Initially, this virus was noted in association with aseptic meningitis, and only a few patients also had exanthem.[557,917] Since the late 1990s, severe epidemic disease with EV 71 has occurred in Taiwan, Singapore, Australia, Malaysia, and Japan. In these epidemics, hand-foot-and-mouth disease is a major finding, and the neurologic disease is more severe than in the past.‡

These phenotypic changes could be the result either of point mutations or of recombination among EVs.§ Chan and AbuBakar[160] presented evidence indicating that a recombination event occurred between EV 71 and coxsackievirus A16.

Pathology

The clinical signs of enteroviral infection vary widely, so great variations in pathology also exist. Because pathologic material generally is available only from patients with fatal illness, this section discusses only the more severe manifestations. Worth emphasizing, however, is that these fatal infections account for just a small portion of all enteroviral infections. The pathologic findings in children with milder infections, such as nonspecific febrile illness, have not been described.

Coxsackieviruses A

Records of severe illness associated with coxsackieviruses A are rare. Gold and colleagues,[382] in a study of sudden unexpected death in infants, recovered coxsackievirus A4 from the brains of three children. In none of these patients were histologic abnormalities noted in the brain or spinal cord. An adult with a fatal coxsackievirus A7 infection had diffuse pancarditis and organized pneumonitis.[46]

Coxsackieviruses B

Of the nonpolio EVs, coxsackieviruses B have been associated most frequently with severe and catastrophic disease. The most common findings in these cases have been myocarditis, meningoencephalitis, or both. Involvement of the adrenals, pancreas, liver, and lungs also has been noted.

Heart

Grossly, the heart usually is enlarged, with dilation of the chambers and flabby musculature.[180,314,364,1081]

Microscopically, the pericardium frequently contains some inflammatory cells along with thickening and edema, and the endocardium may have focal infiltrations of inflammatory cells. The myocardium (Fig. 165-6) is congested and contains infiltrations of inflammatory cells (i.e., lymphocytes, mononuclear cells, reticulum cells, histiocytes, plasma cells, and polymorphonuclear and eosinophil leukocytes). Involvement of the myocardium often is patchy and focal but occasionally diffuse. The muscle shows loss of striation, as well as edema and eosinophilic degeneration. Muscle necrosis without extensive cellular infiltration is a common finding.

Brain and Spinal Cord

The meninges are congested, edematous, and occasionally mildly infiltrated with inflammatory cells.[182,314,727,1081] Lesions in the brain and spinal cord are focal rather than diffuse, but they frequently involve many different areas. The lesions consist of areas of eosinophilic degeneration of cortical cells, clusters of mononuclear and glial cells (Fig. 165-7), and perivascular cuffing. Two children with fatal coxsackieviral B infection (types 2 and 4) had, in addition to typical inflammatory encephalitic lesions, widespread multifocal areas of liquefaction necrosis without inflammation.[305]

Other Organs

The lungs frequently have areas of mild focal pneumonitis with peribronchiolar mononuclear cellular infiltration.[12,108,182,362,726] The liver often is engorged and occasionally contains isolated foci of liver cell necrosis

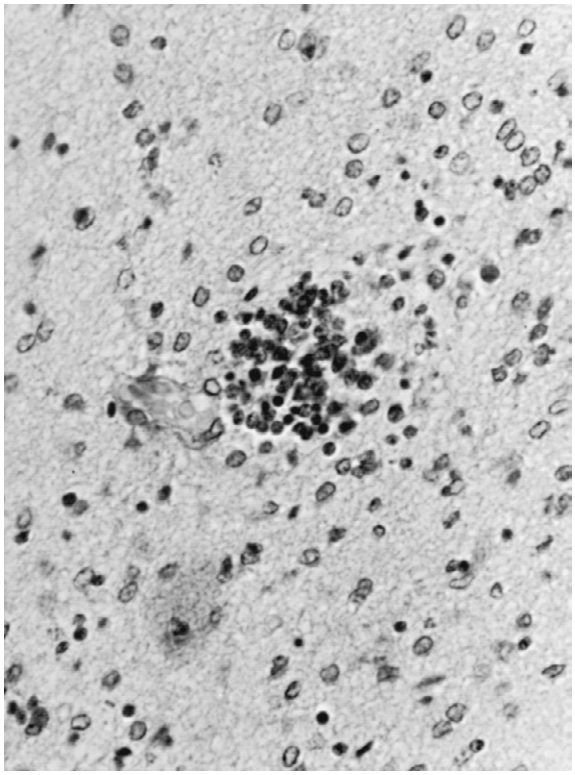

FIGURE 165-7 ■ Coxsackievirus B4 encephalitis in a 9-day-old infant with focal infiltration of mononuclear and glial cells. (From Cherry JD. Enteroviruses. In: Remington JS, Klein JO, editors. *Infectious diseases of the fetus and newborn infant.* Philadelphia, W.B. Saunders, 1976.)

and mononuclear infiltration. In the pancreas, occasional focal degeneration of islet cells occurs. Congestion has been observed in the adrenal glands, along with mild to severe cortical necrosis; inflammatory cells are present.

Echoviruses

Although frequently responsible for illness, echoviruses rarely were associated with fatal infection until relatively recently. In several different reports with eight different echovirus types, hepatic necrosis was a major pathologic finding.* Massive hepatic necrosis has been seen with echoviruses 3, 6, 7, 9, 11, 14, 19, and 21. At autopsy, one infant with echovirus 6 infection had cloudy and thickened leptomeninges, liver necrosis, adrenal and renal hemorrhage, and mild interstitial pneumonitis.[182] One infant with echovirus 9 infection had an enlarged and congested liver with marked central necrosis,[182] and another with this virus had interstitial pneumonitis without liver involvement.[183] Three infants with echovirus 11 infection had renal and adrenal hemorrhage and small vessel thrombi in the renal medulla and in both the medulla and inner cortex of the adrenal glands.[745] These patients' livers were normal. Two infants, one with echovirus 6 and the other with echovirus 31 infection, had only extensive pneumonia.[104,182]

*References 89, 182, 367, 413, 720, 736, 1089.

Enteroviruses

The brain of a child who died of acute encephalitis caused by EV 71 infection was examined.[1094] Grossly, the brain appeared normal, but microscopically, it revealed typical features of acute encephalitis consisting of perivascular cuffing with mixed inflammatory cells, neuronophagia, and inflammatory nodules.

Polioviruses

The neuropathy of poliomyelitis usually is pathognomonic; only certain cells and areas of the neuraxis are susceptible to the virus.[94,217] Neuronal damage is caused directly by virus multiplication, but not all affected neurons are killed. The injury may be reversible, and function may be restored within 3 to 4 weeks after onset. Little histologic evidence of meningeal reaction exists. Perivascular cuffing and some interstitial glial infiltration are present. Histologic sections generally reveal more widespread lesions than would be estimated from the clinical findings. Scattered neurons may undergo considerable destruction without causing clinical disability.

Regions in which neuronal lesions occur are (1) the spinal cord (anterior horn cells chiefly and, to a lesser degree, the intermediate and dorsal horn and dorsal root ganglia), (2) the medulla (vestibular nuclei, cranial nerve nuclei, and the reticular formation that contains the vital centers), (3) the cerebellum (nuclei in the roof and vermis

only), (4) the midbrain (chiefly the gray matter but also the substantia nigra and occasionally the red nucleus), (5) the thalamus and hypothalamus, (6) the pallidum, and (7) the cerebral cortex (motor cortex). The viruses spare the following areas: (1) the entire cerebral cortex except the motor area, (2) the cerebellum except the vermis and deep midline nuclei, and (3) the white matter of the spinal cord. This distribution of lesions permits the physician to establish a histologic diagnosis of poliomyelitis.

Extraneural disease usually is a secondary phenomenon. Bronchopulmonary changes such as aspiration pneumonia, atelectasis, and purulent bronchitis may occur because of impaired coughing and decreased thoracic movement. Cardiovascular changes may result in hypertension, cardiac failure, and pulmonary edema. Prolonged immobilization leads to negative nitrogen and calcium balance, along with urinary lithiasis, renal failure, hypertension with encephalopathy, and seizures. Treatment itself may cause untoward complications, such as urinary tract infection (after catheterization), decubitus ulcers, and psychotic disturbances. Ulcerations in the alimentary tract may result in serious bleeding and occasional perforation. Respiratory failure culminates in respiratory acidosis and anoxic changes.

Parechoviruses

Although parechoviral infections have a broad spectrum of clinical manifestations, including encephalitis and sepsis-like neonatal disease, pathologic data are not available.[1,76,95,620,1049]

CLINICAL MANIFESTATIONS: NONPOLIO ENTEROVIRUSES, PARECHOVIRUSES, AND SAFFOLD VIRUSES

Nonpolio enteroviral, parechoviral and Saffold viral infections are exceedingly common, and the spectrum of disease is protean. Many of the clinical-virologic associations listed in Tables 165-5 through 165-19 are based on a limited number of cases. Because EVs, PeVs, and SAFVs frequently are carried asymptomatically in the gastrointestinal tract for relatively long periods, some of the observed illnesses and the viruses concomitantly recovered may not have a cause-and-effect relationship. However, repeated observations since the 1960s have supported many virus–illness associations, even though their occurrence has been sporadic.

Few specific EV, PeV, or SAFV diseases exist, but, rather, various interrelated syndromes and anatomically associated illnesses are reported. Many illnesses and syndromes can be caused by different viral types, and most types are capable of inducing a variety of clinical syndromes. Conversely, certain specific coxsackieviral and echoviral types have clinical characteristics that facilitate an etiologic diagnosis.

Since the late 1980s, few careful studies have been conducted in which specific clinical findings were correlated with individual enteroviral types. This paucity was fostered by the expense of serotyping and the lack of using inoculation of suckling mice for isolation of virus. The increased use of polymerase chain reaction (PCR) also has contributed to the lack of identification of manifestations of disease by specific viral type. This situation is unfortunate because the clinical manifestations caused by specific viral types are not constant, and disease severity varies by specific enteroviral type.

Asymptomatic Infection

Because researchers have known that 90 to 95 percent of poliovirus infections are not recognized clinically, they have assumed that most infections with EVs, PeVs, and SAFVs are asymptomatic. This opinion is strengthened by the finding that these viruses can be recovered frequently from the stools of healthy children. However, relatively few data are available on the rate of asymptomatic infection with nonpolio EVs, PeVs, and SAFVs. All too frequently, isolation of EVs and PeVs from stool is equated with asymptomatic infection. This assumption is an error because illness, if it takes place, occurs shortly after the acquisition of virus and is short-lived; a particular infection may have been associated with a nonspecific illness 2 or 3 months before a stool specimen is obtained in a surveillance program. Unfortunately, in several studies involving controlled population groups in which accurate clinical expression rates could have been determined, clinical observations apparently were of secondary importance to the investigators.[182,365,366,368,590] The data available suggest differences in clinical expression among coxsackieviral and echoviral types.

Table 165-5 lists the approximate frequency of asymptomatic infections with selected coxsackieviruses and echoviruses. As can be seen, the rates vary among the group as a whole and even within specific types. Overall, approximately half, and perhaps more, of all nonpolio enteroviral infections appear to be associated with clinical

PeV, Parechoviruses.

manifestations. In general, the more carefully clinical symptoms are examined, the smaller is the percentage of truly asymptomatic infections. Clinical expression also is related inversely to age. With coxsackievirus A16, asymptomatic infection occurs in only approximately 10 percent of children younger than 5 years of age, whereas rates are higher in older children and adults.[10,182] Sabin[894] reported no asymptomatic infections in infants with echovirus 18, and Nishmi and Yodfat[770] noted fewer than 20 percent of infections without illness in children younger than 8 years of age during an echovirus 4 epidemic. At the other extreme, Clemmer and associates[225] reported that 96 percent of infections with coxsackievirus B3 were asymptomatic. In other studies, the illness rate of coxsackievirus B3 was 60 to 75 percent. Extensive seroepidemiologic studies by Zoll and colleagues[1114] and Galama and associates[348] of SAFV types 2 and 3 indicate that infection is very common in young children with these viruses. Because other studies have only occasionally noted clinical associations with these viruses, it appears that Saffold viral infections are most often asymptotic.*

Nonspecific Febrile Illness

Nonspecific febrile illness is the most common manifestation of coxsackieviral and echoviral infection (Table 165-6). All viral types cause this clinical finding, but its frequency varies considerably among the individual viruses.

The onset of illness usually is abrupt, without a prodrome. In young children, the initial finding is fever and associated malaise. In older children, headache generally is noted. The temperature ranges between 38.3° and 40°C (101° and 104°F) and has a mean duration of 3 days. In some instances, the fever is biphasic; it occurs for 1 day, is absent for 2 to 3 days, and then recurs for an additional 2 to 4 days. In many young children, the only manifestation of illness is fever, and its presence is discovered by chance by a parent.

Malaise and anorexia often are related to the degree of temperature elevation, as is headache in older patients. Sore throat is a common complaint, but an inflamed pharynx is not seen on examination. Nausea and vomiting occasionally occur at the onset of illness, as does mild abdominal discomfort. One or two loose stools may be noted. Generalized myalgia also is observed, and children complain of a scratchy feeling in the throat.

Physical examination usually yields benign findings. Minimal conjunctivitis, infection of the pharynx, and cervical lymphadenitis may be present. The duration of illness varies from 24 hours to approximately 6 days, with an average of 3 to 4 days. The white blood cell count (WBC) count is normal. EVs, particularly coxsackieviruses A, are significant causes of febrile seizures in young children.[468] An SAFV was noted in a stool sample from a child with a fever of unknown origin.[531]

Respiratory Manifestations

Common Cold

Although numerous coxsackieviruses and echoviruses have been recovered from children with mild upper respiratory tract infections, only rarely do the illnesses qualify as common colds (see Table 165-6). (The common

*References 2, 90, 205, 282, 450, 501, 502, 531, 564, 763, 856, 857, 1009, 1010, 1093.

cold is an acute illness with nasal stuffiness, rhinitis, no objective evidence of pharyngitis, and no or minimal fever.) In most instances, significant fever (temperature >38.3°C [>101°F]) is associated with enteroviral infections and usually some degree of pharyngitis.

Coxsackievirus A21 is the only EV that clearly qualifies as a common cold virus.[183,522] This agent has produced epidemics of mild respiratory illness in military populations. In adult volunteers, instillation of this virus in the nose has resulted in the common cold syndrome. Epidemic disease has not been observed in children. Other viruses that have been associated with the common cold syndrome include echoviruses 2 and 20 and coxsackieviruses B1, B2, B3, B4, B5, and A24.[182]

Pharyngitis (Pharyngitis, Tonsillitis, Tonsillopharyngitis, and Nasopharyngitis)

Pharyngitis is a common clinical manifestation of coxsackieviral and echoviral infection. Probably all EVs on occasion cause mild pharyngitis. The most common coxsackieviruses and echoviruses associated with pharyngitis are as follows: coxsackieviruses A9, B1, B2, B3, B4, and B5; echoviruses 2, 4, 6, 9, 11, 16, 19, 25, and 30; and EV 71.*

Pharyngitis in coxsackievirus and echovirus infections frequently is associated with other clinical findings, such as meningitis, pleurodynia, and exanthem. These other manifestations become more important than pharyngitis in individual cases in the minds of parents as well as clinicians.

Pharyngitis caused by coxsackieviruses and echoviruses usually is abrupt in onset, without a prodrome. Although pharyngeal involvement is present at the onset of disease, the initial complaint usually is fever. The temperature usually ranges between 38.3° and 40°C (101° and 104°F), but higher temperatures are not unusual. In general, fever tends to be more pronounced in younger patients. Young children have malaise and anorexia. School-age children complain of headache and myalgia. Sore throat, coryza and vomiting, diarrhea, or a combination thereof also may be noted.

Examination of the tonsils and pharynx shows varying degrees of erythema. In some cases, only infection is noted, whereas in others, severe pharyngitis with patches of exudate is seen. The usual duration of uncomplicated coxsackieviral or echoviral pharyngitis is 3 to 6 days. Routine laboratory study is of minimal value in enteroviral pharyngitis; the total WBC count may be normal or slightly elevated with a normal differential determination. Throat culture rules out disease caused by group A streptococci.

SAFV type 2 was noted in 13 children with pharyngitis and 12 children with tonsillitis in a Japanese study.[501]

Other Intraoral Manifestations

Herpangina. The onset of herpangina is typical of most EV infections and is characterized by the sudden awareness of fever.[809,1046,1108,1109] No characteristic prodrome usually exists, but young children may be irritable and occasionally listless and anorexic for a few hours before the febrile state is recognized. The initial temperature can be variable, with a range from normal to 41°C (106°F). In general, the temperature tends to be higher in younger patients. Breese noted that the most common temperature in young children was between 39.5° and 40°C (103° and 104°F). Older children frequently complain of headache and backache. Vomiting occurs in approximately 25 percent of children younger than 5 years. In one outbreak of illness caused by coxsackievirus A4,[328] initial symptoms were anorexia and drooling (100%); sore throat (50%); coryza (45%); headache (18%); and vomiting, diarrhea, or both (36%).

In most instances of herpangina, the oropharyngeal lesions are present on the first examination at the time of fever or shortly after fever is noted. In the coxsackievirus A4 outbreak described by Forman and Cherry,[328] the enanthem was not observed until 24 to 48 hours after the onset of initial nonspecific symptoms. The characteristic lesions in herpangina are small (1 to 2 mm) vesicles and ulcers. These lesions apparently start as papules, become vesicular, and then ulcerate in a short but variable period. In my experience (J. D. C.), the lesions most commonly observed are ulcers. Breese[105] noted in some children seen early in the course of the illness that a petechial appearance preceded the appearance of typical vesicular-ulcerative enanthem.

The lesions usually are discrete, with an average of 5 per patient; some patients will have only 1 or 2 lesions, whereas others may have 14 or more. When seen early, the vesicular lesions are observed to enlarge from 1 to 2 mm to 3 to 4 mm during a 2- to 3-day period.[809] Each vesicular and ulcerative lesion is surrounded by an erythematous ring that varies in size up to 10 mm in diameter. The most common site of the lesions is the anterior tonsillar pillars. Lesions also occur on the soft palate, uvula, tonsils, and pharyngeal wall and occasionally on the posterior buccal surfaces. In some cases, additional lesions have been noted on the dorsum or tip of the tongue. However, by definition, cases in which the primary involvement is on the tongue or anterior mouth and in which the lesions are of a general size greater than 5 mm are not considered to be herpangina.

Aside from the specific lesions, the remainder of the throat appears normal, minimally injected, or mildly erythematous. The usual duration of signs and symptoms is 3 to 6 days. Most cases of herpangina are mild and without complications, but aseptic meningitis and other more severe enteroviral manifestations also occur occasionally. Severe neurologic manifestations have been observed in children with herpangina caused by EV 71.[162,165,453,591] During epidemic disease in Taiwan in 1998, children with herpangina and aseptic meningitis, acute flaccid paralysis, and rhombencephalitis were described.[453,473] In one study, a biphasic course was described, with herpangina occurring first and neurologic manifestations 2 to 5 days later.[450]

EVs, PeVs, and SAFVs found in association with sporadic or epidemic herpangina occurrence are presented in Table 165-7.

Acute Lymphonodular Pharyngitis. In 1962, Steigman and colleagues[959] reported a unique enanthem associated with coxsackievirus A10 infection. The lesions had the typical distribution of herpangina; they were papular, discrete, 3 mm in diameter, and surrounded by a zone of erythema. The lesions were white to yellow and persisted for 6 to 10 days. This entity has not been reported again, although coxsackievirus A10 has been noted in association with hand-foot-and-mouth disease.[182,926]

Stomatitis and Other Lesions in the Anterior of the Mouth. The main enteroviral cause of stomatitis and ulcerative lesions in the anterior of the mouth is coxsackievirus A16, and the clinical entity is hand-foot-and-mouth disease. This condition is presented in detail later in this chapter. Worth mentioning here, however, is that occasionally enanthem occurs without the exanthem and this enanthem also has been associated with other coxsackieviruses (A5, A9, A10, B2, B5), echovirus 33, and EV 71.*

In echovirus 9 infection, Tyrrell and colleagues[1014] reported six children with a unique enanthem: painless whitish dots, ulcers, or vesicles on the buccal surfaces near the Stensen duct. These investigators also noted the occasional occurrence of similar lesions under the tongue.

Deseda-Tous and colleagues[267] reported an adolescent with hemorrhagic vesicular lesions on the pharynx, mucosal surfaces, and tongue in association with an echovirus 11 infection. Clarke and Stott[220] observed reddish macules on the buccal mucosa of a patient with echovirus 20 infection, and Cherry and Jahn[187] noted a child with hand-foot-and-mouth disease in whom the buccal lesions suggested Koplik spots, although the lesions were larger and yellower in this patient.

Parotitis

Parotitis in association with herpangina and coxsackievirus A infection was reported in 1957 by Howlett and associates.[471] In 1960, Kraus[596] described two additional cases, and Bertaggia and associates[88] and Winsser and Altieri[1078] noted parotitis in association with coxsackieviruses B3 and B4, respectively. Three patients with acute hemorrhagic conjunctivitis and parotitis caused by EV 70 also have been reported.[913]

Croup

In large studies of respiratory illness in young children, croup is associated sporadically with coxsackieviral and echoviral infection.[170,182,334,373,1064] In general, these illnesses are mild in contrast to croup caused by parainfluenza and influenza viruses.

An outbreak of croup associated with echovirus 11 in a daycare center was reported.[822] In this instance, 17/53 ill children were found to be infected with the U strain of echovirus 11. A subsequent study noted the same virus in 4 children with croup.[823] Croup also was reported in outbreaks of coxsackievirus B5 infection.[42,236] Other specific agents associated with croup include coxsackieviruses A9 and B4 and echoviruses 4 and 21.[182]

Bronchitis

An acute febrile illness with cough, rhonchi, and referred breath sounds occasionally is a sporadic manifestation of enteroviral infection. A specific association of coxsackieviruses B1 and B4, echoviruses 8, 12, 13, and 14, and PeV 1 has been found.[170,182,236,292,294] A SAFV type 2 was noted in one child with bronchitis.[501]

Bronchiolitis and Infectious Asthma

Coxsackieviruses and echoviruses have been associated sporadically with bronchiolitis, infectious asthma, and the precipitation of asthmatic attacks in atopic children.* Epidemic disease has not been observed, and the illnesses usually have been mild.

*References 182, 263, 285, 324, 649, 924.

*References 170, 182, 292, 334, 373, 395, 458, 1064.

Pneumonia

In general, studies of respiratory tract infections in children, sporadic coxsackieviruses, and echoviruses have been noted in 1 to 7 percent of patients with pneumonia and positive viral cultures.[170,182,334,373] Specific virus types include coxsackieviruses A9, A16, B1, B2, B3, B4, B5, and B6; echoviruses 6, 7, 9, 11, 12, 19, 20, and 30; and EV 71.*

In only three instances can an outbreak of pneumonia caused by specific viruses be suggested to have occurred. During the summer of 1959, Lerner and colleagues[632] noted that 3/15 children infected with coxsackievirus A9 had pneumonia. The patients with pneumonia had a vesicular rash, and one of these children died.

Eckert and associates[292] observed 6 children with coxsackievirus B1 infection and pneumonia during the summer of 1963. These illnesses were not described further, although the mean WBC count in 12 children who had lower respiratory tract infections with coxsackieviruses B was reported as 11,383 with a normal differential. All children were hospitalized.

Goldwater[384] reported a coxsackievirus B6 outbreak in south Australia during the summer of 1992 to 1993. Twenty-seven patients had pneumonia associated with high fever and severe cough that lasted several weeks. In addition to the fatal case of coxsackievirus A9 infection described by Lerner and colleagues,[632] deaths have resulted from infection with coxsackieviruses B1, B5, and A16.[323,509,1088]

In the Philippines in 2009, 21 children with EV 68, severe respiratory tract infections, and presumed pneumonia were noted[493] All children had cough and chest in-drawing. Two deaths occurred.

Pleurodynia (Bornholm Disease)

Epidemic pleurodynia† is an illness that was noted first in 1735 by Hannaeus, a Danish physician.[419] Not until the late 19th century, however, did the illness receive further attention in the medical literature. At this time, several epidemics in Scandinavian countries were described.[182,245,322] Although Finsen referred to the disease as *pleurodynia*, others who designated outbreaks used geographic names, such as Skien disease, Bamle disease, Drangedal disease, and Bornholm disease, or descriptive names such as epidemic myalgia, devil's grippe, epidemic diaphragmatic spasm, or epidemic benign pleurisy.[388] In 1933, Sylvest[975] published the classic monograph on the subject, and from this publication the name Bornholm disease (from Bornholm Island, a Danish island in the Baltic Sea) came to be associated with the illness. The enteroviral origin of epidemic pleurodynia was established in 1949.[244,1057]

Historically, pleurodynia is an epidemic disease, but sporadic cases do occur. A characteristic incubation period of approximately 4 days is followed by the sudden onset of fever and pain. The pain typically is located in the chest or upper part of the abdomen and is muscular in origin and of variable intensity. Occasionally, the pain occurs in other areas of the body. Frequently, the pain is excruciatingly severe and sudden and is associated with profuse sweating, so the patient may appear pale and as though in shock. The pain is spasmodic, with durations varying from a few minutes to several hours. Most commonly, the spasmodic periods last approximately 15 to 30 minutes. During spasms, respirations usually are rapid, shallow, and grunting, suggestive of pneumonia or pleural inflammation. Coughing, sneezing, or deep breathing makes the pain worse. Older children and adults describe the pain as stabbing or knifelike. An older person often fears that a heart attack is occurring.

When pain localizes in the abdomen, it frequently is crampy and suggests colic in a younger child. The child may double over and refuse to walk or move. Occasionally, the abdominal pain in association with a pale, sweaty, shocklike appearance suggests acute intestinal obstruction. Splinting and guarding of the abdomen also lead to consideration of appendicitis and peritonitis.

The fever and pain usually last 1 to 2 days. Frequently, however, the illness is biphasic; after the initial febrile period, the patient is asymptomatic for several days, and then the pain and fever recur. Rarely, patients have several recurrent episodes over the course of several weeks. In these patients, fever is less prominent.

Some degree of tenderness is present in the areas of pain, but frank myositis with muscle swelling is not observed. Pleural friction rubs may be noted on auscultation, and they may appear and disappear with the coming and going of episodes of pain.

In epidemics, both children and adults are afflicted, but most cases occur in persons younger than 30 years. Most children have other symptoms of enteroviral infection, such as anorexia, nausea, vomiting, headache, and sore throat. Routine laboratory study is not very helpful. The WBC count varies considerably, but increased percentages of polymorphonuclear neutrophils and band forms are frequent findings. The erythrocyte sedimentation rate also is inconsistent; normal to extremely high values may be observed. The chest radiograph usually is normal.

Complications in pleurodynia seldom develop. Aseptic meningitis has been noted in some patients, and men have experienced orchitis. Cardiac involvement, in the form of myocarditis and pericarditis, also may complicate pleurodynia.

The major etiologic agents in epidemic pleurodynia are coxsackieviruses B3 and B5.* Other viruses associated with epidemic disease include coxsackieviruses B1 and B2 and echoviruses 1 and 6.[32,182,287] Agents associated with sporadic occurrences of pleurodynia include coxsackieviruses A1, A2, A4, A6, A9, A16, B1, B2, B3, B4, B5, and B6; echoviruses 1, 2, 3, 6, 7, 8, 9, 11, 12, 14, 16, 17, 18, 19, 24, 25, and 30; and PeV 2.†

Pleurodynia rarely is reported today. Because the EVs that cause pleurodynia still circulate, cases probably are overlooked or misdiagnosed. An outbreak caused by coxsackievirus B1 in football players at a public high school

was reported.[492] Unfortunately, no clinical data were presented. In 2005, 28 pediatric patients with pleurodynia were observed in a medical center in Northern Taiwan.[472] This outbreak was due to coxsackievirus B3.

Gastrointestinal Manifestations

Gastrointestinal manifestations occur commonly in enteroviral and parechoviral infections.* Clinical manifestations in addition to vomiting and diarrhea are varied (Table 165-8).

Early studies paid particular attention to diarrheal disease in children. However, when specific studies of infantile diarrhea were undertaken, the enteroviral association was far from clear.[62,182,388,809,1104] The correlation of infection and disease in these studies was compromised by the problem that the main source of culture in study patients and controls was from stool; persistent infection in the bowel rendered separation of controls and ill patients impossible.

Infections with all coxsackieviruses and echoviruses frequently have one or more gastrointestinal symptoms as part of the general illness. The intensity and spectrum do vary among the specific agents, however, and also among strains of particular viral types. In a review of World Health Organization (WHO) virus reports covering a 4-year period, Assaad and Cockburn[34] found that the main clinical sign or symptom was gastrointestinal in 12 percent of coxsackieviral infections and in 6.8 percent of echoviral infections. In another analysis, Assaad and Borecka[33] noted 16 deaths during the period 1967 to 1975 in patients with coxsackievirus and echovirus infections in whom the principal clinical association was gastrointestinal.

In a 20-year survey in Wisconsin, Nelson and colleagues[755] noted that gastrointestinal symptoms occurred in approximately one third of all patients from whom these investigators recovered nonpolio EVs. Morens and colleagues[729] reported that in 4 percent of patients from whom nonpolio EVs were recovered during the 1971 to 1975 period, gastrointestinal disease was the major diagnosis. Horn and coworkers,[458] studying respiratory viral infections, noted that 21.2 percent of subjects from whom EVs were recovered had gastrointestinal complaints.

Vomiting

Vomiting is a common manifestation of infection with many coxsackieviral and echoviral types, but it rarely is the major complaint of the patient or the parent.* The frequency of vomiting during outbreaks of illness caused by coxsackieviruses and echoviruses depends on the specific types of virus and on the major manifestation during a particular outbreak. Table 165-9 presents the frequency of vomiting by viral type. In 14 different enteroviral types, vomiting has been noted as a significant aspect of the illness during disease outbreaks. Except for coxsackievirus A16 infections (hand-foot-and-mouth disease), in which it is an uncommon complaint, vomiting occurs in approximately 50 percent of all patients with epidemic enteroviral disease. Vomiting is noted most commonly in meningitis and least commonly in pleurodynia and uncomplicated exanthematous disease.

Diarrhea

Diarrhea occurs commonly in enteroviral and parechoviral infections, but it usually is just one of many manifestations of systemic illness.* Specific studies of diarrheal disease in infants and children have had varied results; some studies indicate an enteroviral origin, whereas others reveal that coxsackieviruses and echoviruses were recovered from well children at the same prevalence.

Ramos-Alvarez and Olarte[847] carried out an extensive study of diarrheal disease in Mexico City and noted that echoviruses were recovered eight times more frequently from children with diarrhea than from control children without diarrhea. These investigators found that echoviruses 6 and 19 predominated, but types 3, 7, 9, 12, 14, 18, and 21 also were recovered. Pelon and colleagues[813] noted an association between coxsackieviruses B4 and B5

*References 10, 31, 32, 82, 111, 114, 182, 185, 236-239, 265, 317, 318, 383, 388, 404, 414, 415, 421, 545, 546, 556, 569, 582, 609, 622, 629, 672, 681, 684, 689, 747, 807, 808, 827, 831, 836, 846-848, 871, 892, 894, 923, 952, 953, 986, 1062, 1075, 1104, 1105.

and acute diarrhea; they observed a 42 percent coxsackievirus B isolation rate in children with acute diarrhea and a corresponding rate of only 12 percent in those without diarrhea. Goodwin and associates[387] noted echoviruses in the stools of children with diarrhea at twice the rate observed in healthy children. In a study by Yow and colleagues,[1104,1105] no association was found between EVs and infantile diarrhea. Echoviruses were recovered twice as frequently from children ill with diarrhea as from children without gastrointestinal illness.[1105] In Canada, McLean and colleagues[689] could find no association between enteroviral infection and gastroenteritis. In a large study of diarrhea in India, coxsackieviruses A9, B3, and B6 and echoviruses 12 and 21 were recovered more commonly from ill patients than from children without diarrhea.[747]

In several studies of specific diarrhea outbreaks, afflicted persons were noted to be actively infected with a particular virus type. Goldwater and Laws[383] observed three children younger than 6 months who were infected with echovirus 19 and who had gastroenteritis without other signs or symptoms. Klein and colleagues[582] recovered echovirus 11 from the blood of two laboratory workers with acute gastroenteritis. Diarrhea occurred in three of nine volunteers given echovirus 11.[114] Eichenwald and associates[296] and Cramblett and colleagues[236] reported epidemic diarrhea caused by echovirus 18 in neonates. An outbreak of diarrhea associated with coxsackievirus A1 was noted in 7/14 bone marrow transplant recipients during a 3-week period.[1001]

Table 165-10 presents the frequency of diarrhea in outbreaks of specific coxsackieviral and echoviral illnesses. Diarrhea varied with regard to the viruses represented and in different studies with the same agents. Diarrhea in enteroviral disease rarely is severe. In most instances, loose stools occur for a 2- to 4-day period. The stools rarely are watery, never are bloody, and at most number six to eight per day. In two childcare centers, diarrhea associated with a parechoviral infection occurred in 21 percent of the children during a one half year period.[104] The following PeV genotypes have been identified in children with diarrhea: 1, 3, 4, 5, 6, 8, 10, 11.[818-820,1111] SAFVs have been identified in stool samples from children with diarrhea, but a cause-and-effect relationship has not been established.[90,422,564,856,1091]

Constipation

Some degree of constipation is a rather frequent occurrence in many acute infectious illnesses, but evaluation is rendered difficult by the subjective nature of the complaint. In coxsackieviral and echoviral diseases, a short period of constipation may be associated with fever, vomiting, and anorexia early in the course of the illness. This period frequently is followed by mild diarrhea.[114] As noted in Table 165-8, constipation has been reported specifically as a symptom with four coxsackieviral and four echoviral types. Constipation is a particularly common event in children with enteroviral meningitis; it occurs in 10 to 40 percent of cases.*

*References 182, 317, 318, 545, 546, 607.

Abdominal Pain

Abdominal pain is a common symptom in many coxsackieviral and echoviral infections. Table 165-11 lists the frequency of occurrence of abdominal pain and the main characteristic of the illness by virus type. Approximately 10 percent of patients with coxsackievirus A16 hand-foot-and-mouth disease report abdominal pain. In approximately one fourth of patients, many coxsackieviruses and echoviruses associated with meningitis cause abdominal pain.

The magnitude of abdominal pain as a clinical symptom in coxsackieviral and echoviral infections varies considerably. For example, in aseptic meningitis, headache and other neurologic reports overshadow the abdominal symptoms. In other situations, fever and abdominal pain are diagnostically troublesome because of the possible presence of a surgical abdomen (discussed further in the next paragraph). The pain most frequently is periumbilical; it may be either constant or colicky. The fever is most often higher than 38.3°C (101°F).

Peritonitis, Pseudoperitonitis, Appendicitis, Pseudo-obstruction, Mesenteric Adenitis, and Intussusception

Occasionally, coxsackieviruses and echoviruses are associated with illnesses that suggest severe abdominal involvement. Liebman and St. Geme[641] described two children with abdominal findings suggestive of acute appendicitis (i.e., semirigid, tender abdomen, rebound tenderness, and rectal tenderness) who had associated infections with echoviruses 1 and 14. McLean[688] described a surgical abdomen in one child with coxsackievirus B1 infection. In this case, virus was recovered from the peritoneal exudate; at surgery, this boy was found to have peritonitis, but his appendix was normal. Thomas[992] reported a 5-year-old boy with coxsackievirus B5 infection who at surgery was found to have excessive clear peritoneal fluid and markedly enlarged mesenteric lymph nodes. A pregnant woman with acute abdominal pain and rebound tenderness associated with echovirus 8 infection was described.[811]

In immunofluorescence studies, Tobe[997] showed the presence of coxsackievirus B2 and B5 antigens in the mucous membranes and mesenteric lymph nodes of patients with appendicitis more often than in similar studies in control subjects. He suggested that the viral infection acts as a trigger for appendicitis. Bell and Steyn[70] recovered echoviruses 7 and 9 from the mesenteric lymph nodes of children with intussusception.

Hepatitis

Marked liver involvement is not a rare finding in disseminated coxsackieviral and echoviral infections in neonates.* The association of hepatitis and enteroviral infection in older children is defined less clearly but

probably occurs more commonly than generally realized, based on the number of individual cases reported. Caution must be exercised in accepting EVs as the exclusive etiologic agent of hepatitis, however, because hepatitis A virus infection has been ruled out in only a few of the available studies.

Morris and associates[734] described an illness suggestive of a coxsackieviral or echoviral infection in an 18-month-old child who had hyperbilirubinemia and abnormal liver function test results. From this child, coxsackievirus A4 was recovered from blood during the acute illness, and a rise in neutralizing antibody titer to the isolated virus was demonstrated. Chang and Weinstein[169] reported a 3-year-old boy with pharyngitis, urinary abnormalities, and neurologic symptoms who had elevated liver enzyme values (i.e., aspartate transaminase value of 1600 and alanine transaminase value of 1180). Coxsackievirus A9 was recovered from this child's cerebrospinal fluid (CSF), and the child's antibody response to this agent was significant. Coxsackievirus A20 has been associated with clinical hepatitis, and simultaneous infections with coxsackievirus A24 and hepatitis A virus have been demonstrated.[921]

An adult with a coxsackievirus B1 infection had both myocarditis and liver involvement.[11] A similar illness caused by coxsackievirus B3 in a 19-year-old woman was described.[971] An 11-month-old boy had a Reye-like syndrome in conjunction with coxsackievirus B2 infection.[550]

Reye syndrome has been associated with echovirus 3 infection.[429] Siegel and colleagues[940] described a hepatosplenic syndrome in which 15 patients had hepatomegaly and coxsackievirus B5 infection. These patients, most of whom were children, had otherwise typical enteroviral illnesses. Liver function studies were performed in only three instances, and the results were normal.

Echoviruses 1, 3, 4, 6, 7, 9, 11, 14, 20, 21, and 30 have been associated with hepatitis.* Hepatomegaly occurs commonly in enteroviral infections.[185,187,316,609,632] During the period from 1971 through 1975, more than 7000 cases of nonpolio enteroviral infection were reported to the Viral Diseases Division at the CDC.[728] In this group were 13 cases of hepatitis and 6 of Reye syndrome; coxsackieviruses A2 and B4 and echoviruses 14 and 22 were associated with Reye syndrome.

Pancreatitis

One of the effects of coxsackievirus B in suckling mice is extensive infection in the pancreas. As with other similarities of infection between suckling mice and human neonates, generalized coxsackievirus B infection in neonates also is accompanied frequently by extensive pancreatic damage. In contrast, pancreatic involvement in older children and adults is not a common occurrence.[126,743,748,1016] Coxsackieviruses B3, B4, B5, and A9 have been noted. Groeneweg and coworkers[405] described a 3-year-old girl with chronic hereditary pancreatitis associated with a serine protease inhibitor Kazal type 1 gene mutation and a high antibody titer to coxsackievirus type 5.

Diabetes Mellitus

A possible relationship between juvenile diabetes mellitus and the seasonal occurrence of coxsackievirus B4 was suggested in 1969 by Gamble and Taylor.[354] In a second study, Gamble and associates[353] noted that titers of coxsackievirus B4 antibodies in patients with type 1 diabetes mellitus (DM) within 3 months of the onset of disease were higher than those in physiologically normal subjects or in patients with chronic diabetes.

Since the 1960s, many studies in animal models and children have looked at the relationship between juvenile-onset, type 1 DM and coxsackieviruses B.* Between 1973

*References 182, 481, 569, 670, 725, 914.

*References 22, 35, 48, 49, 156, 174, 223, 242, 271, 339, 340, 393, 424, 435, 444, 449, 451, 465, 534, 535, 538, 577, 653-655, 798, 875, 919, 925, 995, 1018, 1024, 1073.

and 1984, 10 case-control studies examined the prevalence of antibody to various coxsackieviruses B in patients with type 1 DM and controls. In 8 of these studies, the prevalence was greater in the patients with type 1 DM. In 3 of these studies, IgM antibody to the coxsackieviruses B was examined, and the prevalence in each was greater in the patients with type 1 DM than in controls. A Finnish study noted that patients with type 1 DM were more likely to have IgA antibodies to coxsackievirus B4 than were controls.[488]

Helfand and associates[435] performed a well-done case-control study of type 1 DM. These investigators found that new-onset cases of type 1 DM in patients 13 to 18 years of age were more likely than were controls to be IgM antibody–positive for 9/14 EV serotypes. The serotypes were coxsackieviruses B2, B3, B4, B5, and B6; coxsackievirus A9; and echoviruses 9, 30, and 34. Green and associates[393] performed a systematic review of published case-control studies relating to coxsackievirus B serology and type 1 DM. In 13 studies that looked at antibody to all coxsackievirus B types, 7 (54%) had significantly more positive antibody values in the cases than in the controls. The findings were less impressive when rates of antibody by specific coxsackievirus B serotypes were compared. However, with coxsackievirus B4, the odds ratio was higher than 1/9 of 17 (53%) comparisons, and this difference was significant in 6 (35%) of the studies.

In an extensive study, Skarsvik and colleagues[947] noted that children with type 1 DM had an impaired type 1 T-cell response against coxsackievirus B4 in contrast to the response in healthy children. The findings led these investigators to suggest that the defect in T-cell function delayed clearance of coxsackievirus B4 and made damage to β cells more likely. In another study involving adults, Varela-Calvino and coworkers[1024] noted that T-cell proliferative responses against the VP2 protein of coxsackievirus B4 was significantly reduced in patients with type 1 DM in contrast to the responses in control subjects.

Cudworth and colleagues[242] noted a correlation between HLA type BW15 and coxsackieviruses B1, B2, B3, and B4 antibodies in patients with type 1 DM. In 1979, Yoon and colleagues[1101] reported the recovery of coxsackievirus B4 from the pancreas of a previously healthy 10-year-old boy who died after being in a diabetic coma. Hindersson and coworkers[451] noted the simultaneous onset of type 1 DM in a mother and her 10-year-old son coincident with a coxsackievirus B5 infection.

Clements and coworkers[223] noted that 9/14 serum samples from children with new-onset type 1 DM were positive for EV RNA by PCR. In contrast, only 4 percent of serum samples from control children had evidence of EV RNA. Recently, Oikarinen and associates[793] conducted a nested case control study involving children in Finland who took part in a type 1 diabetes prediction and prevention study. All case children (N = 38) had progressed to clinical type 1 diabetes. Nondiabetic control children (N = 140) were pairwised matched for sex, birth date, hospital district, and HLA-DP-conferred genetic susceptibility. Serum samples (at 3- to 12-month intervals) were examined for EV RNA. EV RNA-positive samples (5.1%) were significantly more frequent among cases than among controls (1.9%). In another Finnish study involving adults, 50 percent of the patients with type 1 diabetes had RNA evidence of ongoing enteroviral infection in the gut, whereas none of the control subjects had similar infections.[792]

In a murine model, See and Tilles[925] found that a diabetogenic strain of coxsackievirus B4 infection resulted in persistent detection of viral RNA in the pancreases of most infected mice. This persistence of antigen was associated with chronic islet cell inflammation and elevated islet cell antibody levels. Stimulated peritoneal macrophages caused lysis of islet cells either directly or by an antibody-dependent mechanism. A study in prediabetic children found that the presence of EV RNA in serum was a risk factor for development of β-cell autoimmunity and type 1 DM.[655] Glutamic acid decarboxylase (GAD_{65}) is one of the major β-cell target antigens in the autoimmune β-cell damaging process that leads to the development of type 1 DM.[653] Antibody and cellular immunity cross reactivity exists between GAD_{65} and the 2C protein of coxsackievirus B4.[35,653] The results of several studies suggest that enteroviral infections are associated with the development of β-cell autoimmunity and the eventual destruction of islet cells.[121,449,654] Time periods from enteroviral infection to the development of β-cell autoimmunity and the eventual development of type 1 DM from β-cell destruction have a great range that perhaps explains the lack of a more specific seasonally related onset of type 1 DM. A case of neonatal type 1 DM associated with a maternal echovirus 6 infection has been reported.[798]

Eye Findings

Acute Hemorrhagic Conjunctivitis

Although conjunctivitis has been a frequent finding in nonpolio enteroviral illnesses since the 1950s, its occurrence as a dominant symptom has been observed only since the 1960s.[134,182,404,592]

In June 1969, Chatterjee and associates[171] noted an epidemic of acute hemorrhagic conjunctivitis in Accra, Ghana. This disease was nicknamed Apollo 11 disease because it coincided with the time of the Apollo 11 moon landing. Since 1969, many epidemics of acute hemorrhagic conjunctivitis have been described. In most epidemics, EV 70 has been the etiologic agent, but similar epidemics have been caused by a variant of coxsackievirus A24.[218] More recently, this virus has been the cause of more epidemics than has EV 70.* Most epidemics have occurred in tropical and semitropical countries; however, outbreaks have been observed in Minnesota, as well as in Moscow, London, and other European cities.[606,1099] In the continental United States, epidemic disease has occurred in Florida and North Carolina.[136] During epidemics, all age groups are affected, but the highest attack rate is in school-age children.[1052]

*References 122, 139, 146, 224, 379, 565, 604, 806, 853, 987, 1050, 1090.

TABLE 165-12 **Frequency of Conjunctivitis in Outbreaks of Illness Caused by Coxsackieviruses and Echoviruses**

Virus Type	Age Group	Conjunctivitis (%)	Main Characteristics of Illness	References
Coxsackievirus A9	Children	20	Pharyngitis, rash	632
Coxsackievirus A16	Mainly children	0-18	Hand-foot-and-mouth disease	171, 666, 871
Coxsackievirus B2	Mainly children	2	Nonspecific febrile illness, respiratory illness	182
Coxsackievirus B3	Children	2-42	Upper respiratory illness	182
Coxsackievirus B4	Children	25	Upper respiratory illness	182
Coxsackievirus B5	Mainly children	7-50	Rash, meningitis, hepatosplenic illness, respiratory illness, pleurodynia	194, 236, 892, 907
Echovirus 2	Children	25	Rhinorrhea	182
Echovirus 4	Children	Rare	Meningitis	670
Echovirus 9	Mainly children	13-30	Rash, meningitis	140, 182, 899
Echovirus 11	Children	15	Rash	192
Echovirus 16	Children	6-10	Rash	414, 759
Echovirus 30	Mainly children	10-60	Meningitis, nonspecific febrile illness	182, 415, 999

Acute hemorrhagic conjunctivitis has a sudden onset, with severe eye pain and associated photophobia, blurred vision, lacrimation, erythema, and congestion of the eye, as well as edema and chemosis of the lids.[445] Subconjunctival hemorrhages of varying size, frequently transient punctate epithelial keratitis, conjunctival follicles, and preauricular lymphadenopathy are present. The eye discharge initially is serous but becomes mucopurulent with secondary bacterial infection. Systemic symptoms, including fever, are rare manifestations. Within 2 to 3 days after the onset of illness, patients note some improvement, and recovery is usually complete in 7 to 12 days. In a study in American Samoa, researchers found that illness caused by coxsackievirus A24 was somewhat different from that caused by EV 70.[911] In cases caused by coxsackievirus A24, conjunctival hemorrhage was less severe, and upper respiratory and systemic symptoms occurred more frequently. In a study in American Samoa of disease caused by EV 70, researchers found that children 2 to 10 years of age had the highest attack rate, and antibody from previous infection gave only partial protection against symptomatic reinfection.[86]

Occasionally, findings suggestive of pharyngoconjunctival fever have been noted. A few patients have had a poliomyelitis-like illness or polyradiculomyeloneuropathy after EV 70 acute hemorrhagic conjunctivitis.[485,1037] Epidemics are explosive, with spread mainly by the eye-hand-fomite-eye route.

Conjunctivitis Associated with Other Enteroviral Illness

Conjunctivitis is a common minor manifestation of enteroviral illness with several specific agents. Table 165-12 presents the frequency of occurrence of conjunctivitis in selected outbreaks of disease caused by coxsackieviruses and echoviruses. Conjunctivitis was most prevalent in coxsackievirus B3 and B5 and echovirus 9 and 30 infections. In addition to the outbreaks reported in Table 165-12, conjunctivitis has been noted in isolated illnesses associated with echoviruses 1, 6, and 20.[569]

Photophobia

As would be expected, photophobia occurs commonly in aseptic meningitis caused by coxsackieviruses and echoviruses. During epidemic meningitis, researchers have noted it with the following viruses: coxsackievirus A9 and echoviruses 3, 4, 6, 7, 9, 19, and 30.* It is a most common occurrence with echovirus 9 and 30 infections, but the incidence of this complaint varies greatly in different reports. In one echovirus 30 outbreak, 80 percent of the patients studied had photophobia.[1000] On average, 20 percent of patients with meningitis have remarkable photophobia. Photophobia also is associated with pleurodynia caused by coxsackievirus B infections.[892,1048]

Other Eye Findings

Nodular lesions on the palpebral conjunctiva were observed in some patients with coxsackievirus A10 infection and lymphonodular pharyngitis.[959] A corneal ulcer occurred in one patient with hand-foot-and-mouth disease.[667] Optic neuritis was described in a boy with pleurodynia, although the enteroviral origin of the illness was not confirmed in the laboratory.[1012] Keratoconjuctivitis was noted in two boys with echovirus 13 infections.[576] Periorbital edema was observed in one patient with echovirus 9 meningitis. A woman with panuveitis associated with coxsackievirus B3 infection was described.[329] One report detailed monofocal outer retinitis in a 36-year-old man with hand-foot-and-mouth disease.[409] Five extensive outbreaks of uveitis caused by echoviruses 11 and 19 in hospitalized young children were noted in three Siberian cities.[1025] These cases occurred predominately in infants hospitalized for other illnesses such as bronchitis, pneumonia, gastroenteritis, sepsis, dystrophy, and premature birth. Three normal adult patients with anterior uveitis in whom parechovirus

*References 69, 182, 388, 395, 541, 542, 545, 546, 572, 629, 670, 827, 999.

was identified in ocular fluid have been noted.[259] In the same study an adult positive for human immunodeficiency virus (HIV) had panuveitis. Sore eyes and other unspecified eye complaints also have been noted frequently in patients with coxsackieviral and echoviral infections.*

Cardiovascular Manifestations

Pericarditis, Myocarditis, and Dilated Cardiomyopathy

Pericarditis or myocarditis or both have been noted in association with 27 different nonpolio EVs. The relative importance of the different serotypes is presented in Table 165-13. The coxsackieviruses B have been implicated most frequently in heart disease. Coxsackievirus B5 has been the most common causative agent, but types 2, 3, and 4 also have been reported frequently. Of the echoviruses, type 6 has been associated most often with cardiac involvement, but the clinical findings with this agent have been described in only a few cases.

In patients with coxsackievirus B cardiac disease, hepatitis, pneumonia, nephritis, meningitis, and orchitis have been occasional associated findings. In 2007 to 2008, detection of severe neonatal disease (often with myocarditis) associated with coxsackievirus B1 infection was detected.[149,800,1067] These severe cases were due to a single genetic lineage. Sometimes, arrhythmias are the only clinical manifestations of myocarditis.[189,1011] Constrictive pericarditis occurs occasionally.[680] The mortality rate for acute coxsackieviral and echoviral heart disease is unknown, but it is significant. Unfortunately, proper virologic study rarely is performed in nonfatal disease. In the only published follow-up study, researchers found that patients who survived acute coxsackievirus myocarditis usually recovered completely, without any residual disability.[966]

The early descriptions of coxsackievirus B infection with myocarditis in the 1950s and early 1960s indicated acute, usually fulminant illnesses in which a coxsackievirus B serotype could be recovered from multiple sites, such as the throat, stool, and CSF, as well as from the heart and other organs at autopsy.[364,402,568,570,1019] Coxsackieviruses B originally were isolated from suckling mice, and the infection in these mice caused acute, overwhelming fatal infections involving multiple organs, including the heart.[253,527] Coxsackievirus B infections in mice were studied in mouse model systems in the 1950s and 1960s, and researchers found that infections in older mice were affected markedly by the virus strain, mouse genetics, and drugs.[96,470,575] Since the 1970s, studies in mouse model systems have become more sophisticated, but they still depend on specific coxsackievirus B strains and specific mouse strains.†

More recent studies in mouse model systems noted the progression of acute coxsackievirus B infection to chronic infection and cardiomyopathy.[20,454,537,680,841,858] Since the mid-1980s, acute, subacute, and chronic cardiomyopathy has been studied in patients by antigen-detection techniques and newer serologic methods.*

Bowles and colleagues[103] found coxsackievirus B nucleic acid sequences in myocardial biopsy samples from several patients with cardiomyopathy. Muir and colleagues[740] detected EV-specific IgM antibodies in the sera of 9 patients with chronic relapsing pericarditis. Fujioka and coworkers[345] reported positive enteroviral PCR results from endomyocardial biopsy specimens in 6/31 patients (19%) with dilated cardiomyopathy (DCM). Andréoletti and collaborators[23] noted EV RNA in 18/25 samples from the heart tissue of patients with DCM or ischemic cardiomyopathy. However, in two other well-controlled studies, enteroviral RNA could not be identified in endomyocardial biopsy samples or in heart tissue from patients undergoing heart transplantation.[228,642] In 1994, Muir and Archard[737] and Melchers and associates[701] reviewed the evidence for persistent enteroviral infection in chronic medical conditions, including idiopathic DCM. Muir and Archard[737] concluded that persistent enteroviral infection is associated causally with chronic medical conditions, whereas Melchers and colleagues[702] found no clear evidence for enteroviral persistence and the subsequent development of chronic medical conditions.

Since the mid-1990s, additional studies in humans have been performed, with mixed results with regard to the role of coxsackievirus B in the origin of chronic cardiomyopathy. Bowles and associates[101] studied cardiac samples for PCR analysis from 624 patients of all ages with myocarditis and 149 patients with DCM. Enteroviral genome was found in the cardiac samples of 85 patients with myocarditis and in the samples from 12 patients with DCM. The histopathologic findings in 9 of these 12 patients demonstrated borderline or mild findings of inflammatory infiltrates. Another study by investigators in the same group examined 80 explanted hearts from children with end-stage heart disease, and an enteroviral genome was not detected.[335] In another study, Zhang and coworkers[1113] found evidence of enteroviral capsid protein VP1 by immunohistochemical staining in 47/89 patients with DCM. In a study performed in Japan, Fujioka and associates[344] detected EV RNA in 7/30 American patients (23%) and in 15/47 Japanese patients (32%) with DCM. In our opinion, the data in these studies suggest that EVs have a role in some patients with DCM.

The general theme in most contemporary mouse model studies is that damage to the myocardium is not caused by the direct cytopathic effect of the virus, but rather is caused by the cellular immune response of the host. Unfortunately, the mouse model data and the less than definitive data from human studies have led cardiologists and others to think that the model systems are representative of human disease.[315,651] No adequate follow-up studies of survivors of acute enteroviral myocarditis or pericarditis have been conducted. Levi and colleagues[634] compared follow-up cardiac data on 10

adults who had acute myocarditis associated with coxsackieviral infections 42 to 68 months previously with similar cardiac data from normal age- and sex-matched subjects. No statistically significant differences in the two groups were found in the seven tests evaluated.

Orinius[797] performed cardiac examinations on 53 adults who had coxsackievirus B infections 2 to 11 years previously. The initial diagnoses in these 53 patients were meningitis in 33 cases, encephalitis in 3 cases, pleurodynia in 6 cases, pericarditis in 2 cases, and nonspecific complaints in 9 cases. Of this group, the "possibility of cardiomyopathy was established" in 2 (4%) cases. Two patients who previously had pericarditis were normal at follow-up.

Sainani and associates[898] performed follow-up studies on 20 adults and 2 teenagers who had coxsackievirus B myocarditis or pericarditis and found that 5 (23%) patients had chronic heart failure. Unfortunately, the duration of time since the primary illness of the patients was not reported.

Bergström and colleagues[81] performed follow-up examinations on five patients (two teenagers and three adults) who had had enteroviral myopericarditis and found that none had significant symptoms or physical signs. No follow-up data are available for neonates, infants, and children who have had enteroviral myocarditis.

In 1954, Stürup[968] reported a follow-up study of patients admitted to the hospital in 1930 to 1932 with pleurodynia. Of nine patients evaluated, including four who had a history of acute pericarditis, none had constructive pericarditis.

Other Cardiac Manifestations

Several investigators have studied the possible association of coxsackievirus B infection and myocardial infarction.* In many instances, patients with infarction have been demonstrated to have concomitant coxsackievirus B infection.† In controlled studies, the results have varied. Nikoskelainen and associates[769] noted that 9/59 patients with acute myocardial infarction had coxsackievirus B infection, whereas in the control group of 38 patients without infarction, only 1 patient had evidence of infection. Similarly, Nicholls and Thomas[762] found that 26 percent of patients had infections, but no infections were found in the control subjects.

In contrast, five other studies failed to show an increased rate of infection in patients with myocardial infarction in contrast to controls.[396,402,781,830,1083] However, two of these studies were performed during a nonenteroviral season,[830,1083] and in a third study, little coxsackievirus B activity occurred in the community during the study period.[396] Analysis of the available studies indicates that coxsackievirus B infection would appear to have a role in myocardial infarction. In one coxsackievirus B5 infection, inferolateral wall myocardial necrosis occurred, but coronary arteriography did not demonstrate obstruction.[266]

Chandy and associates[161] presented data in which antibody to group B coxsackieviruses was related to rheumatic-like valvular heart disease, and Burch and associates[117] demonstrated coxsackievirus B antigens in rheumatic lesions of the heart. Limson and colleagues[643] could find no association between group B coxsackieviruses and rheumatic fever. Soboleva and associates[949] noted an association between coxsackievirus A13 and rheumatic fever; they reported seven children with concomitant streptococcal and coxsackievirus A13 infection. Children with fulminant EV 71 infection have been noted to have acute left ventricular dysfunction.[159,166,474] A 27-month-old girl who died suddenly was found to have an SAFV identified in the CSF, blood, and myocardium.[763]

A 4-month-old boy who had repair of an atrioventricular septal defect was found to have a coxsackievirus B-2 endocarditis.[92] This virus was recovered from the excised prosthetic patch.

Genitourinary Manifestations

Orchitis and Epididymitis

Group B coxsackieviruses are second only to mumps as causative agents of orchitis.* Coxsackievirus B5 is the virus associated most commonly with this disease, although coxsackieviruses B2 and B4 also have been implicated on many occasions. In almost all instances, orchitis is a secondary event in enteroviral infections. The most common association is with pleurodynia. The illness frequently is biphasic: fever and pleurodynia develop initially, and then apparent recovery is followed by orchitis approximately 2 weeks after onset. Many patients also have epididymitis. In epidemics of disease caused by group B coxsackieviruses, the occurrence of testicular involvement varies considerably. Generally, orchitis occurs infrequently, but in one outbreak of coxsackievirus B2, 17 percent of postpubertal male patients had orchitis, and 7 percent also had epididymitis.[182] Orchitis also is associated frequently with pericarditis and myocarditis. In one instance, coxsackievirus B5 was recovered from a testicular biopsy specimen.[234]

In virtually all instances, testicular involvement has occurred in postpubertal patients, mostly in young adults. In addition to coxsackieviruses B2, B4, and B5, other EVs have been implicated: coxsackieviruses B1 and B3[182,569] and echoviruses 6, 9, and 11.[569,1058] Meningitis and exanthem have been associated with orchitis.

Nephritis

Scattered cases of nephritis associated with nonpolio enteroviral infections have been reported. Bayatpour and colleagues[60] noted acute glomerulonephritis in a 9-year-old boy with an extensive coxsackievirus B4 infection. This child had a concomitant rise in antistreptolysin O titer. Yuceoglu and associates[1106] reported twins with echovirus 9 infection and acute glomerulonephritis; Burch and Colcolough[115] observed a patient with progressive

*References 298, 396, 402, 618, 619, 762, 769, 781, 830, 1083, 1085.
†References 298, 396, 402, 618, 619, 676, 762, 769, 781, 1083, 1085.

*References 31, 182, 234, 337, 404, 569, 729, 923, 973, 1060.

fatal pancarditis and nephritis in whom coxsackievirus B4 antigen was found in the kidneys. Mesangiolytic glomerulonephritis associated with an echovirus 6 infection was described in an infant with immune deficiency.[476]

Other Genitourinary Findings

Hemolytic-uremic syndrome has been associated with virologic or serologic evidence of infection with coxsackieviruses A2, A4, A9, A10, A16, A21 and B1 to B6; echoviruses 4, 6, and 7; and PeV 1.* De Petris and colleagues[261] demonstrated titer rises to various EVs in patients with hemolytic-uremic syndrome who were positive or negative for infections with verocytotoxin-producing *Escherichia coli*. Other abnormal renal or urinary findings in nonpolio enteroviral infections include acute oliguric renal failure with coxsackievirus B5[30]; pyuria, hematuria, or proteinuria with echoviruses 1, 6, and 9 and coxsackievirus B5[182,546,629,898,915]; and hemorrhagic cystitis.[729] A 7-year-old girl with coxsackievirus A10 infection had vaginal ulcerative lesions,[718] and Wassermann test results have been falsely positive in patients with echovirus 9 and coxsackievirus B5 infections.[840]

Hematologic Findings

In 1968, Horwitz and Moore[464] described an outbreak of infectious lymphocytosis during which 27 mentally handicapped children were studied. The mean WBC count of the study group patients was 57,200; lymphocytes accounted for at least 50 percent of the total in all cases. Approximately half of the patients had low-grade fever, and 15/27 had moderate diarrhea. A nontypeable EV suggestive of coxsackievirus group A was recovered from the ill patients, and neutralizing antibody to a strain (EVU-16) of the isolated virus developed in 31 percent of the patients in whom serologic studies were performed.[406,465]

Letsas and colleagues[633] reported a 17-year-old-boy with fulminant myocarditis and hemophagocytic syndrome. Over the course of a 3-day period, his hematocrit decreased from 40.9 to 31.7 percent, and his platelet count went from 90,000 to 38,000/mm^3. Examination of the bone marrow revealed many mature histiocytes with active hemophagocytosis. The patient improved dramatically with inotropic and intravenous immunoglobulin (IVIG) treatment. Katsibardi and coworkers[548] reported the occurrence of hemophagocytic syndrome associated with enteroviral infections in three children with malignancies; in spite of IVIG and pleconaril treatment, all cases had a fatal outcome.

Muscle and Joint Manifestations

Arthritis

During the period from 1971 to 1975, during which EVs were recovered from 7075 persons in the United States, 9 instances of rheumatic disease were reported[729]; although not clearly specified, 3 patients apparently had arthritis. Blotzer and Myers[91] noted an adult with echovirus 9 infection and the concomitant onset of arthritis that persisted for 3 months. Echovirus 9 was recovered from the synovial fluid of a man with acute monocytic arthritis,[601] and one adult and one adolescent had serologic evidence of coxsackievirus B4 infection in association with the onset of rheumatoid arthritis–like illness.[487]

Myositis

Because group A coxsackieviruses routinely cause myositis in suckling mice, a reasonable approach is to suspect a similar clinical manifestation in people. Myalgia also is a common complaint in illnesses caused by many coxsackieviruses and echoviruses.[31,182,337,415,608,692] However, almost no direct (i.e., demonstration of virus in muscle) or indirect (i.e., elevations in muscle enzymes) evidence of muscle involvement in routine enteroviral illnesses exists. Of the nine patients with rheumatic disease described by Morens and colleagues,[729] six apparently had myositis; in one instance, coxsackievirus A2 was implicated, and in another patient with polymyositis, coxsackievirus A9 was the related agent. Three patients with echovirus 18 infection and polymyositis have been reported.[558] Acute rhabdomyolysis in one adult and myositis, myoglobinemia, and myoglobinuria in another adult have been associated with echovirus 9 infection.[515,532] Christensen and associates[216] noted that children with dermatomyositis were more likely to have serum antibody to one or more coxsackieviruses B than were control children. Chou and Gutmann[212] noted EV-like particles in the muscles of two patients with fatal dermatomyositis; Tang and colleagues[984] demonstrated coxsackievirus A9 in the muscles of an 11-year-old girl with chronic myopathy. Using both PCR and dot-blot hybridization assays, Fox and colleagues[333] could not find evidence of persistent enteroviral infection in 32 adults with inflammatory muscle disease (1 patient with dermatomyositis and 31 patients with polymyositis).

Yousef and coworkers[1102] reported EV RNA in biopsy specimens from 6/13 patients (46%) with idiopathic polymyositis or dermatomyositis but in no samples from 13 patients with other muscle disorders. Behan and associates[61] looked for picornavirus RNA in biopsy specimens from 41 patients with inflammatory myopathy, but all results were negative.

Dekel and associates[264] reported a 4-year-old girl with localized thigh swelling caused by coxsackievirus A21. On muscle biopsy, perivascular infiltrates were noted, but the muscle fibers were not affected. Widespread edema was found in the muscle.

Skin Manifestations

Nonpolio EVs as a group are a common cause of a variety of skin manifestations.[180,1061,1065] In the summer and fall, these viruses are the leading cause of exanthems. Variation in the clinical expression rate of exanthem and in the age of the host is marked among the various viral types. In general, dermatologic expression is related inversely to the age of the infected patient. The frequency of

*References 36, 261, 372, 782, 854, 855.

exanthem and common associated illnesses by viral type are presented in Table 165-14.

Coxsackievirus A2

Rash associated with coxsackievirus A2 has occurred rarely. Febrile illness with exanthem in conjunction with coxsackievirus A2 infection was observed in Cincinnati in 1957; no details of this outbreak were presented.[894] Assaad and Cockburn[34] reviewed approximately 15,000 enteroviral illnesses for the period from 1967 to 1970 that were reported to the WHO and noted that in 45 instances, skin or mucous membrane lesions associated with coxsackievirus A2 infection were the main clinical manifestations.

Coxsackievirus A3

One case was reported, but no details are available.[725]

Coxsackievirus A4

Exanthem has been noted infrequently with coxsackievirus A4 infection.[34,187,328,734,1110] However, many cases may be missed because this virus grows poorly in tissue culture and suckling mouse inoculation rarely is used in diagnostic laboratories. Six children were observed in one outbreak.[328] All patients initially had herpangina, and then the exanthem appeared concurrently with or after defervescence. It initially was erythematous, maculopapular, and discrete. In some children, the rash resolved within 4 days, but in others it progressed and became vesicular. The vesicular lesions occurred in crops, spread to the extremities, but not the palms and soles, and were yellowish, opaque, and 5 to 10 mm in size. They persisted for 1 to 2 weeks and regressed, with a brownish discoloration. The lesions easily were confused with resolving bug bites. Other manifestations of coxsackievirus A4 infection include an exanthem suggesting combined scarlet fever and rubella,[363] a maculopapular rash that clears with desquamation,[734] and an anaphylactoid, purpura-like rash (Fig. 165-8).[187]

FIGURE 165-8 ■ Erythematous, papular, papulovesicular, and petechial lesions suggestive of anaphylactic purpura in a child with coxsackievirus A4 infection. (See companion Expert Consult website for color version.)

Coxsackievirus A5

During the 4-year period studied by Assaad and Cockburn,[34] coxsackievirus A5 was second only to coxsackievirus A16 in the number of instances for which exanthem or mucous membrane involvement was the main clinical manifestation. Even with this apparent frequency, most instances of exanthem have been sporadic rather than part of an outbreak of exanthematous disease. The most common finding is hand-foot-and-mouth disease, which is not clinically discernible from that caused by coxsackievirus A16.[241,524,328] In one patient, the virus was recovered from vesicular fluid.[324]

Coxsackievirus A6

Recently, severe hand-foot-and-mouth disease has been found in coxsackievirus A6 outbreaks in the United States, Taiwan, Finland, and Japan.[151] In the United States, there were 63 cases noted between November 7, 2011 and February 29, 2012. In California, cases continued to occur in the spring and summer of 2012 (Carol Glaser, California, 2013, Department of Public Health, personal communication). Lesions in this coxsackievirus A6 infection have often been bullous and involved extensive regions of the body. Shedding of nails occurred in two patients.

Coxsackievirus A7

Coxsackievirus A7 was recovered from one child with a morbilliform rash and aseptic meningitis.[398] An adult with a fatal coxsackievirus 7 infection had pancarditis, pneumonia, and hand-foot-and-mouth disease.[46]

Coxsackievirus A9

Coxsackievirus A9 is a common cause of exanthem (Figs. 165-9 and 165-10).* In contrast to coxsackievirus A16 and echovirus 9, in which rates of clinical exanthem expression are high, the rate of skin manifestations in coxsackievirus A9 infection is low. A review of 259 coxsackievirus A9 infections in 1970 revealed an exanthem rate of 4 percent.[182] Most cases of coxsackievirus A9 exanthem occur sporadically, although a few outbreaks have been described.[192,631,778]

Skin manifestations in coxsackievirus A9 infection have been interesting and varied. The most common rash illness is characterized by fever and an erythematous, maculopapular rash that starts on the face and neck and spreads to the trunk and extremities. Aseptic meningitis is a common associated finding.

In 1960, Lerner and colleagues[632] reported on 11 children with exanthem associated with coxsackievirus A9 infection. Of the patients, 6 had vesicular lesions and 2 patients had associated viral pneumonia. Since 1960, vesicular exanthem has been noted on several occasions.[182,192,482] Most commonly, illnesses have been described as hand-foot-and-mouth disease, but when the reports were analyzed, the rashes were vesicular but not always in a peripheral pattern.

FIGURE 165-10 ■ Petechial and purpuric rash in a child with coxsackievirus A9 infection. (See companion Expert Consult website for color version.)

Papular urticaria and large urticarial lesions have been an occasional manifestation of coxsackievirus A9 infection (see Fig. 165-9).[187,192] Other manifestations include Stevens-Johnson syndrome and a severe illness simulating meningococcemia (see Fig. 165-10).[187,729]

Coxsackievirus A10

The most common exanthematous illness associated with coxsackievirus A10 infection is hand-foot-and-mouth disease.* Stevens-Johnson syndrome was associated with coxsackievirus A10 infection in one instance,[182] and a child with ulcerative genital lesions also was reported.[718]

Coxsackievirus A16

In the WHO review of enteroviral infections for the 4-year period from 1967 through 1970, coxsackievirus A16 was associated with almost half of all skin or mucous membrane diseases. Coxsackievirus A16 is the major cause of hand-foot-and-mouth disease (Figs. 165-11 through 165-14). Of historical interest is that hand-foot-and-mouth disease apparently was a new clinical entity in 1956.[777] It was noted in sporadic outbreaks until approximately

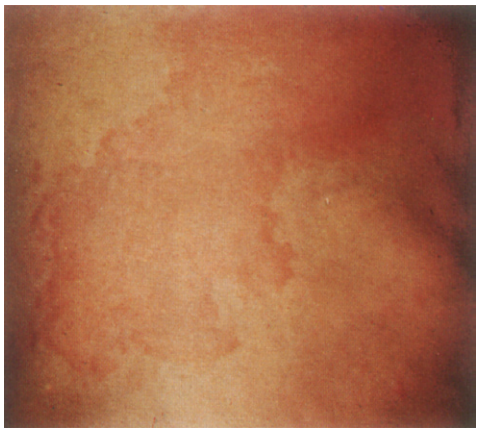

FIGURE 165-14 ■ Acute urticaria in a child with hand, foot, and mouth syndrome caused by coxsackievirus A16 infection. (See companion Expert Consult website for color version.)

1963, and since that time it has been a regularly recurring disease throughout the world.* Serologic data suggest that coxsackievirus A16 was not in wide circulation until approximately 1963.[185]

The signs and symptoms of coxsackievirus A16 hand-foot-and-mouth disease are recorded in Table 165-15. All illnesses have a typically enteroviral pattern with a short incubation period (4 to 6 days) and a summer and fall seasonal pattern. The clinical expression rate of the enanthem-exanthem complex is high—close to 100 percent in young children, 38 percent in schoolchildren, and 11 percent in adults.[730] Exanthem occurs more commonly in children, but in adults, the rash occurs more frequently with coxsackievirus A16 than with any of the other enteroviral agents.

Illness is ushered in with a mild prodromal fever, anorexia, malaise, and frequently a sore mouth. Enanthem occurs 1 to 2 days after the onset of fever, and the exanthem appears shortly thereafter. Of the cutaneous lesions, oral lesions are present more consistently than lesions of the skin. Because of this prevalence, illness, particularly in adults, is identified mistakenly as aphthous stomatitis (canker sores) or herpes simplex virus (HSV) infection. The intraoral lesions are ulcerative and average approximately 4 to 8 mm. The tongue and buccal mucosa are involved most frequently.

As noted in Table 165-15, the hands are involved more commonly than the feet. Buttock lesions also occur frequently, but they usually do not progress to vesiculation. The lesions on the hands and feet generally are vesicular and vary in size from 3 to 7 mm; they typically occur more commonly on the dorsal surfaces but frequently on the palms and soles, as well. The vesicles contain virus, but cytologic examination usually does not reveal diagnostic findings. These lesions clear by absorption of the fluid in approximately 1 week.

Of considerable interest is the frequent association of coxsackievirus A16 with subacute, chronic, and recurring skin lesions.[307,753] Evans and Waddington[307] described an 84-year-old woman with chronic recurring skin lesions of more than 2 years' duration. Nankervis and associates[753] noted both subacute and recurring lesions in children. Higgins and Crow[446] reported a 31-year-old woman with Darier disease who had a Kaposi varicelliform eruption caused by coxsackievirus A16, and a similar illness was noted in a 1-year-old boy with eczema.[746] One child with a Gianotti-Crosti–like eruption (papular acrodermatitis of childhood) associated with coxsackievirus A16 infection was described.[510]

From Cherry JD. Newer viral exanthems. *Adv Pediatr* 1969;**16**:233-86.
*Data from references 16, 186, 328, 341, 667, 698, 866, 872.

Coxsackievirus B1

Exanthem occasionally occurs in coxsackievirus B1 infections.* The most common cutaneous finding is an erythematous maculopapular eruption that is discrete. Two children with illnesses suggestive of hand-foot-and-mouth disease have been observed.[187]

Coxsackievirus B2

Coxsackievirus B2–associated exanthem is a rare occurrence. Maculopapular, vesicular, and petechial lesions have been noted.[31,34,328]

Coxsackievirus B3

Exanthem occasionally is reported as a sporadic event in coxsackievirus B3 infections, and a small outbreak

*References 34, 182, 187, 191, 263, 662.

occurred in one instance.* Erythematous maculopapular eruptions occur most commonly, but petechial rash illnesses suggestive of meningococcemia also have been observed. Hand-foot-and-mouth disease was reported in one child,[631] and another child had a more generalized vesicular eruption. An adult with recurrent Hand-foot-and-mouth disease had a rise in neutralizing antibody titer to coxsackievirus B3.[232]

Coxsackievirus B4

Although cutaneous manifestations with coxsackievirus B4 were noted as frequently as were those associated with coxsackieviruses B1, B2, and B3,[34,182] few clinical descriptions exist.[545,571] Morbilliform, petechial, and urticarial rashes have been described.

Coxsackievirus B5

Of the group B coxsackieviruses, type B5 is noted most frequently to have skin manifestations.† The rash usually is maculopapular; petechial lesions are observed occasionally, and one child with urticaria was reported.[193] Several children studied by Cherry and colleagues[193] had a roseola-like illness pattern. During outbreaks of coxsackievirus B5 illness, approximately 10 percent of young children have an exanthem. Many patients have concomitant aseptic meningitis. One adult patient with recurrent hand-foot-and-mouth disease had serologic evidence of coxsackievirus B5 infection.

Coxsackievirus B6

Goldwater[384] identified 97 children and adults with coxsackievirus B6 infection. The most prominent finding in these cases was cough and pneumonia. Twenty patients had exanthems; the rash was morbilliform and was associated with high fever and cough.

Echovirus 1

Exanthem and conjunctivitis have been associated with echovirus 1 infection in several children.[683]

Echovirus 2

Exanthem occasionally occurs with echovirus 2 infection.[182,897,957] The rash has been erythematous macular in some instances but usually is maculopapular and discrete. Most children have had associated fever and pharyngitis.

Echovirus 3

Exanthem was noted in 2/29 children with echovirus 3 infection.[429] In both instances, the rashes were petechial; most patients in this outbreak had aseptic meningitis. Details of other echovirus 3 infections and exanthems are lacking.[31,462]

*References 31, 34, 124, 232, 318, 421, 480, 631, 1107.
†References 34, 98, 182, 193, 232, 265, 408, 431, 772, 829, 831, 907, 940, 963, 967, 974, 1075.

Echovirus 4

Echovirus 4 is a common cause of epidemic aseptic meningitis, and exanthem is an associated finding in 10 to 20 percent of pediatric cases.* The rash usually is macular or maculopapular, has its onset 1 to 3 days after the initial fever, and lasts 1 to 2 days. A child with a petechial rash was noted.[545]

Echovirus 5

One major outbreak of echovirus 5 infection with exanthem was described.[368] This outbreak, which involved a maternity unit, resulted in a macular rash in 36 percent of the infants and 14 percent of the mothers. The rash was most prominent on the limbs and buttocks, appeared 24 to 36 hours after the onset of fever, and lasted 2 days. Selwyn and Howitt[932] reported a child who had a macular rash with a zoster distribution. A neonate with sepsis-like illness and exanthem was described.[411]

Echovirus 6

Although echovirus 6 has been one of the more prevalent EVs since the late 1970s, it has been associated only sporadically with exanthematous disease. The following manifestations have been observed: morbilliform,[1031] maculopapular,[691,1075] macular,[677] and papulopustular exanthems[546]; Stevens-Johnson syndrome[1034]; and pityriasis rosea in an adult and a child.[546] Meade and Chang[696] reported an interesting zoster-like eruption in a 7-year-old boy in whom echovirus 6 was recovered from several bullae.

Echovirus 7

Echovirus 7 has been associated occasionally with exanthem.[34,246,513,725] In one outbreak of aseptic meningitis, 5/13 patients had erythematous maculopapular rashes that occurred during fever.[513] One child with a discrete maculopapular rash and thrombocytopenia was described.[683] The case of a 37-year-old woman with echovirus 7 infection, leukocytoclastic vasculitis, and palpable purpura was reported.[200]

Echovirus 9

Since the 1960s, echovirus 9 has been the most prevalent nonpolio EV, and exanthem is a common clinical manifestation (Table 165-16, Fig. 165-15).† Nonspecific febrile illness and aseptic meningitis are the usual major manifestations of echovirus 9 infection. Exanthem occurs in approximately one third of cases. The prevalence of exanthem is related inversely to age; 57 percent of children younger than 5 years of age have a rash, whereas only 6 percent of those older than 10 years have similar cutaneous findings.[629] The rash usually is rubelliform, but

in addition or as the sole manifestation, petechiae are common findings. Rash and fever generally appear at approximately the same time, and frequently the illness closely mimics meningococcemia. The rash usually lasts approximately 3 to 5 days. In one instance, the rash progressed to a vesicular stage.[626]

Echovirus 11

Exanthem occasionally occurs with echovirus 11 infection, and it varies considerably in appearance.* The most notable lesions have been bug bite–like vesicles and urticaria.[194] A child with subacute recurrent vesicular lesions[194] and a woman with a disseminated vesicular eruption were reported.[267]

*References 34, 114, 182, 194, 267, 923.

Echovirus 13

One child with a maculopapular eruption was described.[457] During an outbreak of echovirus 13 aseptic meningitis in Israel, 15 patients had a concomitant exanthem.[951]

Echovirus 14

Echovirus 14 is a rare cause of exanthem, and few details are available.[34,897] One child with a scarlatiniform eruption and aseptic meningitis was reported.[897]

Echovirus 16

The first of the enteroviral exanthematous diseases to be described was that caused by echovirus 16. It initially was studied by Neva and Enders[758] and, later, Enders and colleagues,[302] and the illness was called *Boston exanthem*. Two outbreaks of echovirus 16 infection with exanthem were documented by Neva[757] in 1951 and by Neva and Zuffante[762] in 1954, and another occurred in Paris in 1960.[234] Since then, Boston exanthem has been reported only once. Seven cases were observed in 1974.[414]

The exanthem associated with echovirus 16 infection is erythematous, maculopapular, and discrete and is similar to that of other enteroviral infections. What has been unique with echovirus 16 infection is the relationship of rash with fever. Frequently, the illness resembles roseola in that the rash occurs at the time of or after defervescence.[180,414] Ulcerative lesions on the soft palate and tonsillar pillars (herpangina) sometimes have been observed.

Echovirus 17

Rash is an occasional occurrence in echovirus 17 infection.[34,111,187,190] In one outbreak, transient erythematous rashes were noted.[111] In cases that one of us (J. D. C.) studied, papular, maculopapular, and papulovesicular lesions were noted; two patients had herpangitic enanthems, and one had aseptic meningitis.[187,190]

Echovirus 18

Kennett and associates[558] described an extensive epidemic of echovirus 18 infection in which aseptic meningitis with or without exanthem was the major finding. In 15 patients, exanthem was the chief complaint. The rash was described as rubelliform. Most patients were children, but adults also had exanthem.

Echovirus 19

In one extensive epidemic of echovirus 19 infection, exanthem was a common occurrence.[229] Fifty percent of children younger than 6 months of age had exanthem, and many of these infants presented a picture of septicemia with peripheral circulatory failure. Rash occurred in adults and older children, but the percentage decreased with age. The rash usually was erythematous, maculopapular, and discrete. It started on the face and upper part of the trunk and spread to the extremities. Fever occurred in all cases, and meningitis and signs of upper respiratory

tract involvement were noted frequently. In another outbreak of echovirus 19 infection, 33 percent of those infected had exanthem,[383] whereas in an outbreak studied by Cramblett and colleagues,[237] exanthem was a rare finding.

Echovirus 21

A 19-day-old infant with aseptic meningitis and rash was reported.[209]

Echovirus 24

A 4-month-old infant had rash and aseptic meningitis as a result of echovirus 24 infection.[209]

Echovirus 25

Echovirus 25 has been associated with an array of different skin manifestations.[67,186,407,733,751] In one epidemic of febrile pharyngitis, approximately one third of the patients had exanthem.[733] The rash usually was maculopapular and discrete, but occasionally it displayed a morbilliform confluence. The rash most frequently occurred during the period of defervescence.

Of considerable interest are two children with acute hemangioma-like lesions.[186] The lesions were erythematous and papular and surrounded by a 1- to 4-mm–wide halo of blanched-appearing skin. The center of each lesion had a bright red dot that suggested a dilated capillary or terminal arteriole. The whole lesion blanched with pinpoint pressure applied to its middle.

Echovirus 30

Echovirus 30 is a common cause of epidemic aseptic meningitis, and exanthem occasionally is noted concomitantly. The rash is macular or maculopapular.*

Echovirus 32

Two children with echovirus 32 infection and hemangioma-like lesions were described by Cherry and colleagues.[191] Some lesions seemed to be composed of many dilated capillaries; they easily blanched with pressure.

Echovirus 33

Four patients with aseptic meningitis and echovirus 33 infection also had exanthem.[544,555] Two adults had vesicular lesions that suggested HSV infection.[263]

Enterovirus 71

Kennett and associates[557] in Australia studied 49 patients with EV 71 infection and noted exanthem in 11. Six patients had aseptic meningitis, and rash was the predominant complaint in 5 patients. The exanthems varied: some were erythematous maculopapular, some vesicular, and some a combination of lesions. Two children had hand-foot-and-mouth disease, and a single child had a florid, diffuse erythematous rash. Since the 1970s, outbreaks and epidemics of hand-foot-and-mouth disease caused by EV 71 have been noted throughout the world.* Most notable have been epidemics in Asian-Pacific countries. In addition to hand-foot-and-mouth disease, these illnesses also have severe encephalitic manifestations.

*References 34, 182, 495, 540, 624, 999, 1093.

Parechoviruses

Exanthem has been noted in association with PeV infections on several occasions. In some reports, genotypes have been reported,[83,504,800,931,1020] whereas in others only PeV is indicated.[50,825,1027,1028,1080] In one study that included 110 PeV infections, 9.1 percent had unspecified exanthems and, in addition, 6.4 percent had hand-foot-and-mouth disease.[504] Genotypes included types 1 and 3. In a study by Selvarargan and associates[931] of CNS infections with PeV type 3, 60.3 percent had associated maculopapular exanthems. A morbilliform rash has been described in three infants with genotype 1 infections.[83] Genotypes 1 to 6 have all had infections associated with rash.

Clinical Exanthematous Manifestations and Syndromes

The major clinical exanthematous manifestations and syndromes of coxsackieviruses and echoviruses are presented in Table 165-17. Unusual findings include hemangioma-like lesions with echoviruses 25 and 32, anaphylactoid purpura with coxsackievirus A4 and echoviruses 9 and 18, zoster-like rash with echoviruses 5 and 6, pityriasis-like rash with echovirus 6, and chronic or recurrent rash with coxsackievirus A16 and echovirus 11.

Neurologic Manifestations

Neurologic illness is a frequent manifestation of infection with most EVs and PeV. The most common illness is aseptic meningitis, but encephalitis and other manifestations also occur. Parechoviral neurologic manifestations are particularly common and significant in neonates and during the first 3 months of life (these will be discussed in the section on neonatal infections). The prevalence of nonpolio EVs and PeVs in the various clinical syndromes is presented in Table 165-18.

Aseptic Meningitis

Aseptic meningitis caused by EVs occurs both in epidemics and as isolated cases. The etiologic agents most often associated with epidemic disease are presented in Table 165-19. Epidemic disease has occurred most commonly with coxsackievirus B5 and echoviruses 4, 6, 9, 13, and 30. In general, illness occurs more frequently in children, but if a specific outbreak is large, adults also are involved. Virtually all patients have fever and pharyngitis; other respiratory manifestations occur commonly. Rash is a frequent occurrence but varies with the specific viral

agents. Between one third and half of all patients with echovirus 9 meningitis have exanthem. Abdominal pain is a common symptom in patients with epidemic enteroviral aseptic meningitis.

Except for rash, herpangina, pleurodynia, or myocarditis, little else occurs clinically to help identify the origin in a sporadic case of aseptic meningitis. Initial symptoms include fever, headache, malaise, nausea, and vomiting. The headache usually is frontal or generalized; adolescents and adults frequently note retrobulbar pain. Pain in the neck, back, and legs occurs commonly. Abdominal pain is noted in approximately one fifth of patients, but this symptom varies with the specific etiologic viral type. Photophobia is a common occurrence.

Physical examination reveals a temperature in the range of 38° to 40° C (100.4° to 104° F). Skin rash occurs often and usually is erythematous, maculopapular, and discrete. Frequently, particularly with echovirus 9 infection, the rash is petechial and suggests meningococcemia. Hand-foot-and-mouth disease is a common event in cases of aseptic meningitis caused by EV 71 infection.[159,166,453,591,694] Pharyngitis occurs frequently. Generalized muscle stiffness or spasm usually is observed, although the degree varies considerably; the Kernig and Brudzinski signs are positive in fewer than half of the cases. Deep tendon reflexes usually are normal. In one study, 9 percent of children with enteroviral meningitis had the syndrome of inappropriate secretion of antidiuretic hormone.[175] The onset of this syndrome was noted 36 hours after admission to the hospital, and it usually lasted less than 2 days.

Examination of CSF reveals considerable variation among patients and in the same patient on repeated examination. CSF leukocyte counts vary from a few cells to a few thousand per cubic millimeter; the median is in the range of 100 to 500 cells/mm^3. The percentage of neutrophils also varies greatly. Initial examinations frequently reveal a predominance of neutrophils, but rarely more than 90 percent, as seen in bacterial disease. Usually, a range between 30 and 60 percent neutrophils is found on initial examination. Repeated examinations of CSF demonstrate an increasing percentage of mononuclear cells. Dagan and colleagues[247] observed that the rate of isolation of virus from the CSF in enteroviral meningitis was directly proportional to the number of leukocytes in the fluid. Dalal and associates[252] found that children with echovirus 4 meningitis had elevated values of interleukin (IL)-6 and interferon in the CSF and that the IL-6 value correlated with the CSF leukocyte values.

CSF protein levels usually are elevated mildly, and glucose concentrations usually are normal; hypoglycorrhachia rarely occurs.* Occasionally, the CSF findings suggest tuberculosis meningitis with mononuclear pleocytosis, hypoglycorrhachia, and elevated protein levels.[669] A child with coxsackievirus B4 meningitis had eosinophils in the CSF.[195] The results of other routine laboratory studies such as the WBC count occasionally are abnormal but are not helpful diagnostically.

The duration of illness varies significantly. In most patients, the temperature returns to normal within 4 to 6 days, and disability as a result of neurologic involvement lasts 1 to 2 weeks. Occasionally, the pattern of illness is biphasic; an initial period with fever, headache, nausea, vomiting, and muscle aches and pains of a few days' duration is followed by general recovery and then

*References 38, 196, 297, 609, 628, 673, 933, 941, 945, 969.

a return to the same symptoms in addition to more pronounced neurologic involvement.

Wilfert and associates[1069] performed a longitudinal assessment of children who had enteroviral meningitis early in life and found that receptive language functioning was significantly worse than that of children in a control group without meningitis. In another study, Sells and colleagues[930] examined the long-term effects of CNS enteroviral infection in 19 children. Of this group, 11 were free of detectable abnormalities, 5 had possible defects, and 3 had definite neurologic sequelae. In more recent studies, patients who have had meningitis have performed as well as controls in follow-up developmental evaluations.[80,817,882]

Encephalitis

In the United States, approximately 2500 cases of encephalitis per year, on average, are reported to the CDC.[137] Of this group, only approximately 2 percent of these patients demonstrate an enteroviral origin. However, the seasonal pattern of disease and the absence of arboviral activity in many geographic locations suggest that 500 to 1000 cases of enteroviral encephalitis actually occur each year in the United States. The prevalence of coxsackieviruses and echoviruses as etiologic agents in encephalitis is presented in Table 165-18. Echovirus 9 is the most frequent cause of enteroviral encephalitis. Other enteroviral types commonly associated are echoviruses 4, 6, 11, and 30 and coxsackievirus B5. Echoviruses 4, 6, and 11 have been noted most frequently over a long period.

In general, the prognosis in encephalitis caused by enteroviral infection is good, but fatalities do occur. The viral types that have been isolated from the brain or CSF in fatal cases are coxsackieviruses B3 and B6; echoviruses 2, 9, 17, and 25; and EV 71.[404,569] First noted in Japan in the 1970s were outbreaks of hand-foot-and-mouth disease associated with a diverse array of encephalitic manifestations.[499] Since the mid-1970s, epidemics of hand-foot-and-mouth disease with encephalitis have been occurring in Asian-Pacific countries.*

In an outbreak in Taiwan in 1998, 30/78 (38%) patients with severe illness had encephalitis and 25 of these patients with encephalitis also had pulmonary edema or hemorrhage, 2 had myocarditis, and 1 had acute flaccid paralysis.[453] In another study, 30/34 children with CNS involvement had brain stem encephalitis and 9 of this group (30%) died.[1044] Children who recovered from EV 71 encephalitis associated with cardiopulmonary failure often had neurologic sequelae with delayed neurodevelopment, reduced cognitive function, and attention-deficit/hyperactivity–related problems.[164,835]

Paralysis

Paralysis caused by anterior horn cell disease occasionally results from infection with nonpolio EVs. In contrast to the prevalence of poliovirus, which in the prevaccine era resulted in epidemic paralytic disease, paralysis caused by nonpolio EVs usually is a sporadic event. Coxsackievirus A7 has been associated with outbreaks of paralytic disease on three occasions.[402,40,1038] Many cases of illness similar to poliomyelitis have occurred during outbreaks and epidemics of illness caused by EV 71.[16,256,371,433,502,707,907] Paralytic disease also has been noted during epidemics of acute hemorrhagic conjunctivitis caused by EV 70.[1040,1102]

GUILLAIN-BARRÉ SYNDROME AND TRANSVERSE MYELITIS

As Table 165–17 shows, many coxsackieviruses and echoviruses apparently have been associated with Guillain-Barré syndrome. In general, no specific viral types appear to cause the disease. Rather, the disease occurs sporadically in association with the prevalent enteroviral types.

Other Neurologic Illnesses

Cerebellar ataxia has been associated with coxsackieviruses A4, A7, A9, B3, and B4 and echoviruses 6, 9, and 16 (see Table 165-18). A 16-month-old boy with ataxia was found to have an SAFV in the CSF and in a fecal sample.[763] Scott[923] specifically commented on peripheral neuritis with echovirus 9 infection. Coxsackievirus A9 has been associated with focal encephalitis and acute hemiplegia on two occasions,[154,182] and echovirus 25 infection was noted in a 5-year-old boy with focal encephalitis and subacute hemichorea.[815] Coxsackievirus B4 was isolated from the CSF of a 22-year-old woman with intracranial hypertension,[1086] and postencephalitis Parkinson syndrome occurring after an episode of coxsackievirus B2 meningoencephalitis was described.[1039] Coxsackievirus B3 and EV 71 infections have been associated with opsoclonus-myoclonus.[599] The case of a 4-year-old boy with "Alice in Wonderland" syndrome (complex symptoms of perceptual distortion) associated with coxsackievirus B1 infection was described.[1043]

Phillips and colleagues[824] and Barrett and associates[53] noted the simultaneous occurrence of enteroviral and St. Louis encephalitis viral infection in the same community. In six instances, dual infections occurred, and the afflicted children tended to have more serious illnesses. Ribai and colleagues[863] noted an 18 month-old boy with transient cerebral arteriopathy and an enteroviral infection. The child had aphasia, right hemiplegia, and seizures, which occurred intermittently over a 3-day period.

Ergul and associates[303] described a 7-year-old boy with vestibular neuritis from whom enteroviral RNA was found in both the CSF and a nasopharyngeal sample. Multiple attacks of enteroviral aseptic meningitis in the same individuals have been noted occasionally.[585,750]

Woodall and associates[1084] found conserved enteroviral sequences in spinal cords from subjects with sporadic motor neuron disease and from one patient with possible familial motor neuron disease. Berger and associates[80] noted EV RNA sequences in spinal cord specimens from 13/17 patients with amyotrophic lateral sclerosis, but Walker and colleagues[1038] could not duplicate these findings in a study of 20 spinal cord specimens from similar

*References 127, 157, 158, 163, 165,166, 178, 208, 343, 453, 467, 472, 474, 475, 499, 540, 591, 639, 645-648, 656, 679, 694, 695, 773, 794, 796, 835, 1040-1042, 1096.

patients. Simonsen and coworkers[943] noted an outbreak of vertigo in Wyoming in August of 1992 in which IgM antibody studies suggested an enteroviral origin.

Chronic Fatigue Syndrome and Fibromyalgia

From molecular techniques and antibody prevalence data, chronic enteroviral infections have been suggested to play a role in the chronic fatigue and postviral fatigue syndromes.[25,123,224,737,1103] However, these findings have not been confirmed by other investigators.[702,715,973] More recently, Douche-Aourik and associates[275] found enteroviral RNA in muscle biopsies from 4/30 (13%) patients with fibromyalgia or chronic fatigue syndrome but in no biopsy samples from 29 healthy subjects. However, in none of the 4 positive samples could the presence of VP1 enteroviral capsid protein be demonstrated using a specific monoclonal antibody. In another study, Lane and colleagues[615] found enteroviral RNA in muscle biopsy samples of 10/48 patients (20.8%) with chronic fatigue syndrome and in no samples from 29 controls. These investigators also found that 9 of the 10 subjects with positive muscle biopsies had abnormal lactate responses to exercise in the subanaerobic threshold exercise test. In an editorial relating to these data, Dalakas[249] warned that similar findings in the past were "epiphenomenal" because EVs are ubiquitous in humans and technical flaws inherently connected to contamination in laboratories working with these viruses are inevitable.

The biggest proponents for a causal role of EV in chronic fatigue syndrome have been Chia and Chia.[199,201] Although they have had extensive experience with chronic fatigue syndrome and have conducted several studies, none of their data had been adequately controlled.[589] More recently, they have presented data suggesting that some cases of chronic fatigue syndrome are the result of chronic enteroviral infections of the stomach.[202,203]

Sudden Infant Death

Balduzzi and Greendyke[47] recovered coxsackievirus A5 from the stool of a 1-month-old child who experienced sudden infant death. In a similar investigation of sudden infant death, Gold and associates[382] recovered coxsackievirus A4 from the brains of three babies. Coxsackievirus A8 also was recovered from the stool of a child in whom anorexia was noted on the day before death. Coxsackievirus B3 was recovered at the autopsy of an infant who died suddenly on the eighth day of life.[47] Morens and colleagues[729] noted sudden infant death eight times in association with enteroviral infection; PeV was found on two occasions. In a subgroup of infants with sudden unexplained death in whom the "clinical, biologic, and histologic" findings suggested viral infection, evidence of enteroviral infection was found more frequently than in infants without findings of viral infection.[391] Specifically, enteroviral RNA was detected in the respiratory tract in 54 percent of the viral infection group and in none of the group without findings suggestive of viral infection. These results were supported by IgM antibodies to coxsackieviruses B in 56 percent of the first group and in none of the second group. Four infants with suspected sudden infant death syndrome were found to have coxsackievirus B3 myocarditis with minimal histopathologic changes.[269] In five instances of crib death in one study, echovirus 11 was isolated from the lungs in two cases, from the myocardium in one case, and from the nose or feces in the other two cases.[88] Drexler and associates[280] noted RNA evidence of genotype 2 SAFV in the CSF of an infant with sudden infant death syndrome.

Chronic Enteroviral Infections in Immunocompromised Patients

Patients with cell-mediated and combined immunodeficiencies are susceptible to chronic and often fatal infections with many viruses.[350] Patients with agammaglobulinemia and normal cell-mediated function generally survive infections with these same viruses. EVs are the exception, however, in that chronic, unusual infections with a variety of EVs have been reported.* The most common illness is meningoencephalitis, but arthritis and polymyositis are other frequent findings. Echovirus 11 has been the most common cause of chronic infection, but the following other EVs also have been causative: echoviruses 2, 3, 5, 6, 7, 9, 13, 14, 15, 17, 18, 19, 21, 24, 25, 26, 29, 30, and 33; coxsackieviruses A11, A15, B1, B2, and B3; and PeV 1.[687] EVs have been recovered from many other body sites, such as the liver, heart, lung, pancreas, lymph nodes, bone marrow, muscle, throat, and stool, in addition to the CSF.

Several patients with X-linked agammaglobulinemia have had polymyositis-like or dermatomyositis-like syndromes caused by echovirus infections; the following echoviruses have been implicated: types 2, 3, 5, 9, 11, 17, 19, 24, 25, 30, and 33.[52,240,698] The case of a 15-year-old boy with X-linked agammaglobulinemia and chronic arthritis caused by echovirus 11 was reported.[9] Three children with X-linked hyper-IgM syndrome and persistent enteroviral meningoencephalitis were described.[243] Persistent enteroviral infections of the CNS were reported in pediatric and adult patients infected with HIV.[290,803] In addition, enteroviral infections caused deaths in bone marrow transplant recipients.[24,348]

Congenital Infections

Abortion

Landsman and associates[612] studied 2631 pregnancies during an epidemic of echovirus 9 and could find no difference in antibody to echovirus 9 in women who aborted and in those who delivered term infants. A similar study in Finland revealed no increase in the abortion rate in women infected in early pregnancy with echovirus 9.[851] Although coxsackieviral infections occur commonly, epidemics with specific viral types involving large populations have not been studied.

Two women with coxsackievirus A16 hand-foot-and-mouth disease had spontaneous abortions.[791] In one instance, coxsackievirus A16 was recovered from the

*References 9, 87, 93, 231, 240, 243, 286, 289, 304, 412, 416, 442, 547, 687, 885, 1023, 1053, 1055, 1068.

products of conception. Frisk and Diderholm[338] found that 33 percent of women with abortions had IgM antibody to coxsackieviruses B, whereas only 8 percent of controls had similar antibody. In a second, larger study, the same research group confirmed their original findings.[39]

Ljungan virus (a PeV) is endemic in some rodent populations, and it can cause fetal death in these animals. Krous and Langlois[598] and Samsioe and colleagues[903] suggest that this virus may be the cause of some intrauterine deaths in humans. In one study, both PCR and immunohistochemical staining identified Ljungan virus in specimens from five human intrauterine fetal deaths.[903]

Congenital Malformations

In a large prospective study, Brown and Karunas[110] made a serologic search for selected maternal enteroviral infections in association with congenital malformations. Sera from 630 mothers of infants with anomalies and from 1164 mothers of children without defects were studied carefully. Specifically, serologic evidence of infection with coxsackieviruses B1, B2, B3, B4, B5, and A9 and with echoviruses 6 and 9 was sought during the first trimester and during the last 6 months of pregnancy. In this study, infants were examined for 113 specific abnormalities; these anomalies were grouped into 12 categories for analysis. The investigators demonstrated a positive correlation between maternal infection and infant anomaly with coxsackieviruses B2, B3, B4, and A9. The overall anomaly rate associated with first-trimester infection with coxsackievirus B4 was significantly higher than that in controls. Maternal coxsackievirus B2 infection throughout pregnancy, coxsackievirus B4 infection during the first trimester of pregnancy, and infection with at least one of the five group B coxsackieviruses during pregnancy were associated with urogenital anomalies in contrast to controls. Coxsackievirus A9 infection was associated with digestive anomalies and coxsackieviruses B3 and B4 with cardiovascular defects. When coxsackieviruses B were analyzed as a group (B1 to B5), an overall association with congenital heart disease was found; the likelihood of having cardiovascular anomalies was increased when maternal infection with two or more coxsackieviruses B occurred.

Gauntt and colleagues[360] found that ventricular fluid from 4/28 babies with severe anatomic defects contained neutralizing antibody to one or more coxsackievirus B types. In one case, specific IgM antibody to coxsackievirus B6 was demonstrated.

In a serologic study in Scotland, Ross and colleagues[878] found no association between maternal coxsackievirus B infection and fetal developmental anomalies. Elizan and associates[299] were unable to find any relationship between maternal infection with coxsackieviruses B and congenital CNS malformations. In three studies, no association between maternal echovirus 9 infection and congenital malformation was noted.[584,612,851]

Niklasson and associates[768] studied CNS malformations in terminated pregnancies. PeV (Ljungan virus) was diagnosed in 9/10 cases of hydrocephalus and in 5/9 cases of anencephaly, whereas this virus was found in only 1/18 trisomy 21 controls.

Prematurity and Stillbirth

Bates[57] reported an 8-month-old stillborn fetus with calcific pancarditis and hydrops fetalis at autopsy. Fluorescent antibody study revealed coxsackievirus B3 antigen in the myocardium. Burch and colleagues[116] reported three stillborn infants who had fluorescent antibody evidence of coxsackievirus B myocarditis, one each with coxsackieviruses B2, B3, and B4. These investigators also described a premature boy who had histologic and immunofluorescent evidence of cardiac infection with coxsackieviruses B2, B3, and B4; he lived only 24 hours.

Freedman[336] reported the occurrence of a full-term stillbirth in a woman infected with echovirus 11. Because the baby had no pathologic or virologic evidence of infection, Freedman attributed the event to a secondary consequence of maternal infection caused by fever and dehydration rather than primary transplacental infection. In another stillbirth in which echovirus 11 was recovered from amniotic fluid, the fetus was found to have evidence of focal encephalitis, massive adrenal hemorrhage, and diffuse subarachnoid hemorrhage.[948] Echovirus 27 was recovered from amniotic fluid in an intrauterine fetal death at 28 weeks of gestation.[762] A 26-week, 1300-g stillborn fetus with hydrocephalus, fibrotic peritonitis, and hepatosplenomegaly was found by PCR and immunohistochemical study to have an EV 71 infection.[213] A baby of 26 weeks' gestation with nonimmune hydrops fetalis and an intrauterine infection with coxsackievirus B3 was reported by Ouellet and coworkers.[799]

Neonatal Infections

Epidemiology and Pathogenesis

Neonatal infection with EVs and PeVs can result from transplacental viral transmission, contact infection during birth, and human-to-human contact after birth. Transplacental passage of coxsackieviruses and echoviruses at term has been noted on many occasions. Benirschke[71] studied the placentas in three cases of congenital coxsackievirus B disease and could find no histologic evidence of infection. In 1956, Kibrick and Benirschke[570] reported the first case of intrauterine infection with coxsackievirus B3. In this instance, the infant was delivered by cesarean section and became symptomatic several hours after birth. Brightman and associates[106] recovered coxsackievirus B5 from the placenta and rectum of a premature infant. No histologic abnormalities of the placenta were noted.

Berkovich and Smithwick[84] noted an asymptomatic neonate who had specific IgM PeV 1 antibody in cord blood, thus suggesting intrauterine infection with this virus. Hughes and colleagues[481] reported a newborn infant with echovirus 14 infection who had markedly elevated IgM (190 mg/dL) on the sixth day of life. This child probably also was infected in utero. In addition, echovirus 19 has been noted in a transplacentally acquired infection.[821] Other evidence of intrauterine infection has

been presented for coxsackieviruses A4, B1, B2, B3, B4, and B5 and echoviruses 9, 11, and 19.*

Little definitive evidence exists for either ascending infection or contact infection with coxsackieviruses or echoviruses during birth. However, transmission of infection during the birth process seems probable.[179,190,543] The fecal carriage rate of EVs in asymptomatic adult patients varies between 0 and 6 percent or higher in different population groups.[182] Cherry and colleagues[190] reported that in 2/55 mothers (4%), EVs were present in feces shortly after delivery.

Coxsackievirus B5 was recovered from the cervices of four women with febrile illnesses during the third trimester of pregnancy.[860] Echovirus 11 was isolated from the cervix of a mother whose baby became ill on the third day of life with fatal echovirus 11 necrotizing hepatitis.[859] Chang and colleagues[168] detected coxsackievirus B3 in breast milk of two symptomatic mothers, and their babies both suffered severe illnesses with hepatic necrosis and meningitis caused by coxsackievirus B3.

Several epidemics with coxsackieviruses and echoviruses in newborn nurseries have been studied.[106,128,712,745] Brightman and associates[106] observed an epidemic of coxsackievirus B5 in a premature nursery. Their data suggested that the virus was introduced into this nursery by an asymptomatic infant who had been infected in utero. Secondary infections occurred in 12 babies and 2 nurses. The timing of the secondary cases suggested that three generations had occurred and that the nurses had been infected during the second generation. The investigators suggested that the infection had spread from infant to infant and from infant to nurse.

Javett and associates[514] reported an acute epidemic of myocarditis associated with coxsackievirus B3 infection in a Johannesburg maternity home. Unfortunately, no epidemiologic investigation or search for asymptomatic infected infants was performed. However, in analyzing the dates of onset of the illnesses, single infections apparently occurred for five generations, and then five children became ill within a 3-day period.

Kipps and colleagues[579] carried out epidemiologic investigations in two coxsackievirus B3 nursery epidemics. In the first epidemic, the initial infection probably was transmitted from a mother to her baby; this baby then was the source of five secondary cases in newborn infants and one illness in a nurse. Four of the five secondary cases were located on one side of the nursery, but only one crib was close to that of the index baby, and this crib did not adjoin the cribs of the three other contact cases. In the second outbreak, a baby who also was infected by his mother probably introduced the virus into the nursery. The three secondary cases were geographically far removed from the primary case.

Cramblett and colleagues[235] reported an outbreak of echovirus 11 disease in four infants in an intensive care nursery. All infants were in enclosed incubators, and three patients became ill within 24 hours; the fourth child became ill 4 days later. Echovirus 11 was recovered from two members of the nursery staff. These data suggest that transmission from personnel to infants occurred because of inadequate washing of hands.

In another outbreak in an intensive care unit, the initial patient was transferred to the nursery because of severe echovirus 11 disease.[745] After transfer, the senior house officer and a psychologist in the unit were infected. The investigators inferred that these infected personnel spread the disease by respiratory droplet to nine other babies. In another nursery outbreak of echovirus 11, Mertens and colleagues[712] found that the infection spread through close contact between infected newborns and the nurses in the unit. Spread of infection was interrupted with the installation of vigorous hygienic and isolation measures. In an outbreak of echovirus 11 in an intermediate care unit, Kinney and colleagues[578] found that gavage feeding, mouth care, and being a twin were risk factors for acquiring illness.

Many other instances of isolated nursery infections and small outbreaks with coxsackieviruses and echoviruses have been reported. The most consistent source of original nursery infection seems to be transmission from a mother to her baby,* but virus can be introduced into the nursery by hospital personnel.[496,617,974]

In a longitudinal study of neonatal enteroviral infections carried out during the summer and fall of 1981, Jenista andassociates[516] found that the nonpolio enteroviral infection rate was 12.8 percent. Lower socioeconomic status and lack of breast-feeding were found to be risk factors for acquiring infection. Nonpolio enteroviral infections were determined to be a significant cause for readmission of the cohort neonates to the hospital. During a community outbreak of echovirus 11 disease, Modlin[721] found that passive transplacental passage of antibody to neonates prevented the development of severe disease but not mucosal infection.

Clinical Manifestations

Enteroviral and parechoviral infections in neonates result in a wide variety of clinical manifestations ranging from asymptomatic infection to fatal encephalitis and myocarditis.[183] An overview by illness category and prevalence is presented in Table 165-20.

Inapparent Infection. Although inapparent infection probably occurs occasionally with many different EVs, little documentation of this assumption exists. Cherry and colleagues[190] studied 590 normal neonates during a 6-month period and noted only a single asymptomatic infection. This child was infected in utero or immediately thereafter with coxsackievirus B2. The mother had an upper respiratory tract illness 10 days before delivery.

During a survey of perinatal viral infections, 44 babies were found to be infected with PeV 1 in the study period May to December of 1966.[506] The prevalence of virus and the incidence of new infections during this period were fairly uniform. No illness was attributed to PeV 1 infection, and the virus disappeared from the nursery in mid-December. Asymptomatic infections with PeV 1 were

noted on two other occasions.[84,753] Infections without evidence of illness also have been noted with coxsackieviruses A9, B1, B4, and B5 and echoviruses 3, 5, 9, 11, 13, 14, 20, 30, and 31.*

Mild, Nonspecific Febrile Illness. In a review of 338 enteroviral infections in early infancy, 9 percent were classified as nonspecific febrile illnesses.[728] Illness may be sporadic or part of an outbreak with a specific viral type. When the illness is part of an outbreak, the clinical manifestations vary, depending on the viral type; some infants have aseptic meningitis and other signs and symptoms, whereas others simply have nonspecific fever. Specific viruses related to nonspecific fever are listed in Table 165-20. Although by definition illness in this category is mild, awareness that viral infection may be extensive is important. When sought, virus may be isolated from the blood, urine, and CSF of infants with mild illnesses.[55,510] In an outbreak of relatively benign illness caused by echovirus 7 in six neonates, all the infants were found to have high C-reactive protein values.[246]

Sepsis-Like Illness. The main diagnostic problem in neonatal enteroviral and parechoviral infections is differentiation of bacterial from viral disease. Even in an infant with mild, nonspecific fever, bacterial disease must be considered strongly. The sepsis-like illness described here always is alarming. Illness is characterized by fever, poor feeding, abdominal distention, irritability, rash, lethargy, and hypotonia.† Other findings include diarrhea, vomiting, seizures, and apnea. In severe, frequently fatal illnesses, most often caused by echovirus 11 infection, jaundice, hepatitis, disseminated intravascular coagulation (DIC), thrombocytopenia, and hypotension occur.[530,720,736,859]

Sepsis-like illness is a common occurrence. Morens[728] noted its presence in one fifth of 338 enteroviral infections in infants. In an attempt to differentiate bacterial from viral disease, Lake and associates[609] studied 27 infants with enteroviral infection. WBC counts were not helpful because the total count, the number of neutrophils, and the number of band-form neutrophils were elevated in most cases. Of most importance were historical data. Most mothers had suffered a recent febrile, viral-like illness. In addition, other factors often associated with bacterial sepsis, such as prolonged rupture of membranes, prematurity, and low Apgar scores, were unusual findings in the enteroviral infection group. Bone marrow failure developed in a newborn baby boy with a sepsis-like illness caused by echovirus 11 infection.[985] The neutropenia resolved spontaneously, and the thrombocytopenia normalized after treatment with IVIG.

Abzug[5] reviewed the prognosis in 16 neonates who had a sepsis-like illness with hepatitis and coagulopathy. The case-fatality rate was 31 percent. In addition to having hepatitis and coagulopathy, the 5 patients with fatal cases had myocarditis and 3 patients had encephalitis. The follow-up of 6 survivors noted normalization of liver function and platelet counts and the absence of subsequent significant medical problems.

Respiratory Illness. Respiratory complaints generally are overshadowed by other manifestations of neonatal enteroviral disease. Only 7 percent of 338 enteroviral infections in early infancy were classified as respiratory illness in one study.[728] Herpangina has been observed and photographed only once; Chawareewong and associates[173] noted several infants with herpangina and coxsackievirus A5 infection.

Hercík and colleagues[439] reported an epidemic of respiratory illness in 22 neonates associated with echovirus 11 infection. All of these infants had rhinitis and pharyngitis, 50 percent had laryngitis, and 32 percent had interstitial pneumonitis. Berkovich and Pangan[83] studied respiratory illnesses in premature infants and reported 64 babies with illness, 18 of whom had virologic or serologic evidence of PeV 1 infection. In addition, many had high but constant levels of serum antibody to PeV 1. Some of the infants with high antibody levels probably also were infected with PeV 1. The children with proved PeV 1 infection could not be differentiated clinically from those without evidence of such infection. Ninety percent of the infants had coryza, and 39 percent had radiographic evidence of pneumonia.

Except for echoviruses 11 and PeV 1, respiratory illness associated with EVs has occurred sporadically. The following other viruses have been noted: coxsackieviruses A5, A9, B1, B4, and B5 and echoviruses 9, 17, 18, 19, 20, 22, and 31. In the review by Morens,[728] only 7/338 enteroviral infections of infancy were classified as pneumonia. A newborn with an echovirus 11 infection developed meningitis, DIC, and persistent pulmonary hypertension.[1071] Postmortem examination revealed pneumonia, hyaline membranes, pulmonary interstitial emphysema, meningitis, and DIC.

Eichenwald and Kostevalov[295] recovered echovirus 20 from four full-term infants younger than 8 days of age. Although these infants were asymptomatic, they were found to be colonized extensively with staphylococci, and they disseminated these organisms into the air around them. Because of this ability to disseminate staphylococci, they were called *cloud babies*. The investigators thought these cloud babies contributed to the epidemic spread of staphylococci in the nursery. Because active staphylococcal dissemination occurred only when echovirus 20 could be recovered from the nasopharynx, viral–bacterial synergistic activity was thought to be present.

Gastrointestinal Manifestations. Significant gastrointestinal illness occurs in approximately 7 percent of enteroviral infections of infancy.[728] Vomiting and diarrhea occur commonly but usually are only part of the overall illness complex and not the major manifestations. In 1958, Eichenwald and associates[296] described epidemic diarrhea associated with echovirus 18 infection. In a nursery unit of premature infants, 12/21 babies were mildly ill. Neither temperature elevation nor hypothermia occurred. Six infants were lethargic and listless, and moderate abdominal distention developed in 2 infants. The diarrhea lasted from 1 to 5 days; these infants had

*References 183, 182, 296, 310, 368, 496, 505, 516, 617, 735, 974.
†References 50, 414, 426, 609, 825, 931, 1019, 1080, 1087.

five or six watery, greenish stools per day, occasionally expelled explosively. Two infants had a small amount of blood, but no mucus or pus cells, noted in their stools. Five babies in another nursery also had similar diarrheal illness. Echovirus 18 was recovered from all ill infants.

In 22 infants with epidemic respiratory disease caused by echovirus 11, all had vomiting as a manifestation of the illness.[439] Linnemann and colleagues[650] reported vomiting in 36 percent and diarrhea in 7 percent of neonates with echoviral infection. In another study, Lake and associates[609] found diarrhea in 81 percent and vomiting in 33 percent of neonates with nonpolio enteroviral infections.

Hepatitis is an important neonatal nonpolio enteroviral illness. Morens[728] reported that 2 percent of neonates with clinically severe enteroviral disease had hepatitis. Lake and colleagues[609] observed that hepatomegaly was present in 37 percent of neonates with enteroviral infection, and hepatosplenomegaly was observed by Hercík and associates[439] in 12/22 newborns with echovirus 11 respiratory illness.

Severe hepatitis, frequently with hepatic necrosis, has been noted with echoviruses 6, 9, 11, 14, 19, 21, and 30.* Echovirus 11 most often has been associated with severe and usually fatal hepatitis; findings include DIC and thrombocytopenia, as well as apnea, lethargy, poor feeding, and jaundice.

Philip and Larson[821] reported three catastrophic neonatal echovirus 19 infections that resulted in hepatic necrosis and massive terminal hemorrhage. One infant, infected in utero, was symptomatic at birth. The Apgar score was 3, and multiple petechiae were observed. Generalized ecchymoses and apneic episodes occurred, and the infant died at 3.5 hours of age. Thrombocytopenia was noted, and echovirus 19 was isolated from the brain, liver, spleen, and lymph nodes. The other two infants who died of echovirus 19 infection were twins. They were normal during the first 3 days of life but then became mildly cyanotic and lethargic. Shortly thereafter, apneic episodes occurred, and jaundice and petechiae developed. Both twins became oliguric, and they died on the eighth and ninth days of life with severe, terminal gastrointestinal bleeding. Both twins were thrombocytopenic, and virus was recovered from systemic sites in both.

Pancreatitis was found in three of four newborns with coxsackievirus B5 meningitis[588] and in a coxsackievirus B4 infection at autopsy.[1079] In other fatal coxsackievirus B infections, pancreatic involvement has been detected, but clinical manifestations rarely have been observed.

Lake and associates[609] reported three infants with necrotizing enterocolitis. Coxsackievirus B3 was recovered from two of these infants, and coxsackievirus B2 was recovered from the third.

Cardiovascular Manifestations. In contrast to enteroviral cardiac disease in children and adults, in which pericarditis is a common finding, neonatal disease almost always involves the heart muscle. Most cases of neonatal myocarditis are caused by coxsackievirus B infection, and nursery outbreaks have occurred on several occasions. In 1961, Kibrick[568] reviewed the clinical findings in 45 cases of neonatal myocarditis; his findings are summarized in Table 165-21. Of interest is that many of the early experiences, particularly in South Africa, involved catastrophic nursery epidemics. Since the observation in 1972 of five newborns with echovirus 11 infection and myocarditis, no other nursery epidemics have been reported.[278]

TABLE 165-21 **Signs and Symptoms of Neonatal Coxsackievirus B Myocarditis**

Category	Frequency (%)
Feeding difficulty	84
Listlessness	81
Cardiac signs	81
Respiratory distress	75
Cyanosis	72
Fever	70
Pharyngitis	64
Hepatosplenomegaly	53
Biphasic course	35
Central nervous system signs	27
Hemorrhage	13
Jaundice	13
Diarrhea	8

Modified from Kibrick S. Viral infections of the fetus and newborn. *Perspect Virol* 1961;**2**:140-159.

The illness caused by coxsackieviruses B most commonly was abrupt in onset, with symptoms of listlessness, anorexia, and fever. A biphasic pattern was noted in approximately one third of the patients. Progression was rapid, and signs of circulatory failure appeared in a 2-day period. If death did not occur, recovery occasionally was rapid but usually took place gradually over an extended period. Most patients had cardiac findings such as tachycardia, cardiomegaly, electrocardiographic changes, and transitory systolic murmurs. Many patients showed signs of respiratory distress and cyanosis. Approximately one third of the infants had signs suggesting neurologic involvement. Of the 45 cases analyzed by Kibrick,[568] only 12 patients survived.

In an echovirus 11 nursery outbreak reported by Drew,[278] 5/10 babies had tachycardia out of proportion to their fever. Three of these babies had electrocardiograms; supraventricular tachycardia was noted in all, and ST-segment depression was observed in 2 patients' records. Supraventricular tachycardia also has occurred with coxsackievirus B infection.[505] Echovirus 19 has been associated with myocarditis, and coxsackievirus A9 was noted in a child with pericarditis.[237,980]

In the 1970s, neonatal myocarditis caused by EVs was seen less commonly than it was in the 1950s and early 1960s. In his review, Morens[728] noted only two instances among 248 severe neonatal enteroviral illnesses. Chan and Lun[456] reported a neonate with coxsackievirus B4 myocarditis who developed a ventricular aneurysm.

*References 82, 97, 183, 182, 413, 481, 530, 720, 736, 821, 826.

Exanthem. Exanthem as a manifestation of neonatal enteroviral infection has been reported with coxsackieviruses B1, B3, and B5; with echoviruses 4, 5, 7, 9, 11, 16, 17, and 18; and with PeV 1, 3, 4, 5, and 6. In most instances, rash is just a minor manifestation of severe neonatal disease. In 27 infants studied by Lake and colleagues,[609] 41 percent had exanthem. Cutaneous manifestations generally commence between the third and fifth days of illness. The rash usually is macular or maculopapular. Petechial lesions are noted occasionally. Surprisingly, vesicular lesions have not been described, nor has any rash illness in neonates been associated with coxsackievirus A16. Hall and associates[414] reported two neonates with echovirus 16 infections in which the illnesses resembled roseola. These patients had fever for 2 and 3 days, defervescence, and then the appearance of a maculopapular rash.

A newborn with a vesiculopapular-crusted rash on the face, trunk, and extremities caused by coxsackievirus B3 was reported by Theodoridou and associates.[991] It was a congenital infection in which new lesions appeared over the course of a 5-day period, and the total duration of the rash was 10 days.

Neurologic Manifestations. As noted in Table 165-20, neurologic illness has been associated with coxsackieviruses B1, B2, B3, B4, and B5, many echoviruses and PeVs. In neonates, differentiating meningitis from meningoencephalitis usually is difficult. Meningoencephalitis occurs commonly in infants with sepsis-like illness, and postmortem studies revealed many infants with disseminated viral disease (heart, liver, adrenal glands) in addition to CNS involvement. In Morens' review,[728] 50 percent of the patients with enteroviral infection who were analyzed had encephalitis or meningitis.

The initial clinical findings in neonatal meningitis or meningoencephalitis are similar to those in nonspecific febrile illness or sepsis-like illness. Most often, the child is normal and then becomes febrile, anorectic, and lethargic. Jaundice frequently is noted in newborns, and vomiting occurs in neonates of all ages. Less common findings include apnea, tremulousness, and general increased tonicity. Seizures occur occasionally. Extensive white matter injury has been noted in neonatal PeV encephalitis.[1027] This finding can be confused with white matter changes associated with hypoxic-ischemic injuries.

Examination of CSF reveals considerable variation in protein, glucose, and cellular values. In seven newborns with meningitis caused by coxsackievirus B5 studied by Swender and colleagues,[974] the mean CSF protein value was 244 mg/dL, and the highest value was 480 mg/dL. The mean CSF glucose value was 57 mg/dL, and one of the seven infants had pronounced hypoglycorrhachia (a value of 12 mg/dL). The mean CSF leukocyte count in the seven babies was 1069 cells/mm^3, with 67 percent polymorphonuclear cells. The highest cell count was 4526 cells/mm^3, with 85 percent polymorphonuclear cells. In another study involving 28 children younger than 2 months of age in which coxsackievirus B5 was the implicated pathogen, 36 percent of the infants had CSF leukocyte counts of 500 cells/mm^3 or greater.[673] In this same study, only 13 percent of the infants had CSF protein values of 120 mg/dL or greater; 12 percent of the infants had glucose values lower than 40 mg/dL.

In summary, the CSF findings in neonatal nonpolio enteroviral and parechoviral infections frequently are similar to those in bacterial disease. In particular, the most consistent finding in bacterial disease, hypoglycorrhachia, is noted in approximately 10 percent of newborns with enteroviral meningitis.[196,297,609,673,974]

Johnson and associates[525] reported a 1-month-old boy with right-sided facial paralysis and loss of abdominal reflexes. The facial paralysis persisted through convalescence; the reflexes returned to normal within 2 weeks. The boy was infected with coxsackievirus B2.

Euscher and associates[306] detected coxsackievirus RNA in placental tissue from six of seven newborn infants with respiratory difficulties and other manifestations at birth. Of these infants, one died shortly after birth, and the other six suffered neurodevelopmental delays.

CLINICAL MANIFESTATIONS: POLIOVIRUSES

When a susceptible person has had effective contact with a poliovirus, one of several responses may occur, in the following order of frequency: (1) inapparent infection, (2) minor illness (abortive poliomyelitis), (3) nonparalytic poliomyelitis (aseptic meningitis), and (4) paralytic poliomyelitis.* Paralytic poliomyelitis is the most dramatic expression of the infection and the only one clinically recognizable as caused by a poliovirus; it accounts for not more than 1 to 2 percent of infections during epidemics and considerably less under endemic conditions (see Fig. 165-5). The aseptic meningitis syndrome is similarly infrequent; nonspecific "minor illness" is estimated to occur in 4 to 8 percent, and 90 to 95 percent of those infected have inapparent infections. Factors that determine the type of clinical response are poorly understood, but the degree of virulence of the virus and certain host characteristics are important.

Age has a significant effect on patterns of infection; older patients are more likely to have severe paralytic disease and a higher mortality rate. Pregnancy increases the risk, probably primarily because of hormonal factors but also because pregnant women may be exposed more to young children, who are the main sources of contagion. Tonsillectomy in the presence of inapparent infection can precipitate bulbar poliomyelitis; evidence also suggests that tonsillectomy at any time in the past results in enhanced susceptibility to the bulbar form of the disease. Recent diphtheria-tetanus-pertussis vaccination increases the likelihood of development of paralysis; the site of injection and the site of paralysis appear to be correlated. Physical exertion and trauma around the time of onset also increase the risk for severe paralysis, especially in adults.

*References 16, 94, 181, 183, 217, 469, 1100.

Minor Illness (Abortive Poliomyelitis)

The minor illness is mild and nonspecific, with low-grade fever, malaise, anorexia, and sore throat. Physical examination reveals no significant abnormalities, CSF is normal, and recovery occurs within 24 to 72 hours. The illness often is so mild that it goes unrecognized, and patients rarely are seen by a physician.

Nonparalytic Poliomyelitis (Aseptic Meningitis)

The onset of nonparalytic poliomyelitis is associated with vague malaise followed by fever, headache, aching of the muscles, and sometimes hyperesthesia and paresthesia. Anorexia, nausea, vomiting, constipation, or diarrhea also may be present. The temperature rises to 37.8° to 39.5° C (101° to 103° F); stiffness of the neck, back, and hamstrings soon appears.

Approximately two thirds of affected children have a short, symptom-free interlude between the first phase (minor illness) and the second phase (CNS or major illness). This two-phase course occurs less commonly in adults, in whom the evolution of symptoms is more insidious. Nuchal and spinal rigidity is necessary for establishing the diagnosis of nonparalytic poliomyelitis during the second phase.

Physical examination reveals nuchal-spinal signs and changes in superficial and deep reflexes. With cooperative patients, the nuchal-spinal signs are sought first by active tests. The child is asked to sit up unassisted. If doing so causes undue effort, if the knees flex upward, and if the patient writhes a bit from side to side while sitting up and uses the hands on the bed for the tripod supporting position, unmistakable spinal rigidity is present. Still sitting, the patient is asked to flex chin to chest and is observed for nuchal rigidity. Alternatively, from the supine position with the knees held down gently, the patient is asked to sit up and kiss the knees. If the knees draw up sharply or if the maneuver cannot be completed adequately, the patient has stiffness of the spine caused by muscle spasm. If the diagnosis still is uncertain, attempts should be made to elicit the Kernig and Brudzinski signs. Gentle forward flexion of the occiput and neck elicits nuchal rigidity, which may precede spinal rigidity. Head drop may be demonstrated by placing the hands under the patient's shoulders and raising the trunk. Normally, the head follows the plane of the trunk, but in poliomyelitis, it often falls backward limply. The frequency of the head-drop sign, even in nonparalytic poliomyelitis, with no subsequent residuals indicates that it is not caused by true paresis of the neck flexors. In struggling infants, distinguishing voluntary resistance from clinically important involuntary nuchal rigidity may be difficult. One may place the infant's shoulders flush with the edge of the table, support the weight of the occiput in the hand, and then flex the head anteriorly. Nuchal rigidity that persists during this maneuver may be interpreted as involuntary. When not closed, the anterior fontanelle also may be tense or bulging.

In the early stages, the reflexes are normally active and remain so unless paralysis supervenes. Changes in reflexes, either increased or depressed, may precede the onset of weakness by 12 to 24 hours; hence, detecting such changes is important, especially in nonparalytic patients managed at home. The superficial reflexes (i.e., cremasteric and abdominal and the reflexes of the spinal and gluteal muscles) are usually the first to be diminished. The spinal and gluteal reflexes are elicited by tapping segmentally downward on each side of the spine and buttocks. These reflexes may disappear before the abdominal and cremasteric ones. Changes in the deep tendon reflexes, whether exaggerated or depressed, generally occur 8 to 24 hours after depression of the superficial reflexes and indicate impending paresis of the extremities.

Laboratory findings consist of a normal or slightly elevated WBC count and the characteristic CSF changes of aseptic meningitis—approximately 20 to 300 cells, predominantly lymphocytes, a normal glucose level, and a normal or slightly elevated protein level. If a spinal tap is performed in the first few hours after onset, a predominance of polymorphonuclear leukocytes may be seen, but it shifts in 6 to 12 hours to more than 90 percent lymphocytes. If no further progression of clinical signs occurs, the disease remains nonparalytic, the temperature falls to normal, and signs of meningeal irritation gradually disappear. Recovery ensues in 3 to 10 days, depending on the severity of the illness.

Paralytic Poliomyelitis

The manifestations of paralytic poliomyelitis are those enumerated earlier for nonparalytic poliomyelitis in addition to weakness in one or more muscle groups, either skeletal or cranial. Patients in whom paralysis is destined to develop often wear an anxious expression; they are extremely alert, restless, and flushed and appear acutely ill. The fever is higher than that in abortive disease, and the patient may have intense muscle pain. Shortly before actual muscle weakness is detected, the superficial and deep reflexes often diminish or disappear on the affected side. Frequently, a symptom-free interlude of several days occurs between the initial illness phase and the recurrence of symptoms that culminate in paralysis.

The onset of paralysis may be extraordinarily sudden and may progress in a few hours to complete loss of motion in one or more extremities. Asymmetric involvement is typical in milder cases. More gradual spread of weakness also occurs and may continue over a period of 3 to 5 days. Bladder paralysis of 1 to 3 days' duration develops in approximately 20 percent of patients, and bowel atony frequently is noted, occasionally to the point of paralytic ileus. In general, when the fever subsides, no further paralysis is likely to occur. The lower limbs are affected more commonly than are the upper, but in severe cases, quadriplegia and loss of function of the intercostal, abdominal, and trunk muscles with resultant respiratory difficulty may ensue. The superficial and deep reflexes in the affected limbs are lost; twitching of the muscles and diffuse fasciculations may be seen transiently. Sensory abnormalities are rare occurrences.

Flaccid paralysis is the most obvious clinical expression of the neuronal changes. The ensuing muscular atrophy is caused by denervation in addition to the atrophy of disuse. The pain, spasticity, nuchal and spinal rigidity, and hypertonia early in the illness probably are caused by lesions in the brain stem, spinal ganglia, and posterior columns. Respiratory and cardiac arrhythmias, blood pressure and vasomotor changes, and similar manifestations reflect damage to vital centers in the medulla.

On physical examination, the distribution of paralysis characteristically is spotty. To detect mild muscular weakness, one often must apply gentle resistance in opposition to the muscle group being tested. The spinal form has weakness of some of the muscles of the neck, abdomen, trunk, diaphragm, thorax, or extremities. The bulbar form is characterized by weakness in the motor distribution of one or more cranial nerves, with or without dysfunction of the vital centers of respiration and circulation. Patients with bulbar disease often are extremely agitated, even delirious, or they may become stuporous. The 10th cranial nerve nuclei are involved most commonly and result in paralysis of the pharynx, soft palate, and vocal cords. Facial paralysis occurs less commonly; it usually is asymmetric and involves only selected muscle groups. Ocular palsies are unusual findings.

Components of both the bulbar and spinal forms occur together in bulbospinal poliomyelitis. In the encephalitic form of the disease, irritability, disorientation, drowsiness, and coarse tremors not explained by inadequate ventilation are noted. Even during epidemics of poliomyelitis, this form can be recognized only if some peripheral or cranial nerve paralysis coexists or ensues. Hypoxia and hypercapnia caused by inadequate ventilation from respiratory insufficiency may produce disorientation without true encephalitis.

Numerous components acting together may result in insufficiency in ventilation (Table 165-22). The most serious consequences are hypoxia and hypercapnia, which may produce profound effects on many other systems. Respiratory insufficiency should be detected early to diminish its widespread effects, and because the situation may shift rapidly, continued clinical evaluation is essential. Despite weakness of the respiratory muscles, the patient may respond with so much respiratory effort that normal alveolar ventilation is maintained. In fact, the increased effort (associated with anxiety and fear) actually may produce overventilation at the outset and may result in respiratory alkalosis. Such effort is fatiguing and soon leads to respiratory failure.

For clarity, certain terms characterizing patterns of disease need definition. First, *pure spinal poliomyelitis with respiratory insufficiency* refers to tightness, weakness, or paralysis of the respiratory muscles (chiefly the diaphragm and intercostals) without discernible clinical involvement of the cranial nerves or vital centers. The cervical and thoracic spinal cord segments chiefly are involved. Second, *pure bulbar poliomyelitis* refers to paralysis of the motor cranial nerve nuclei with or without involvement of the vital centers that control respiration, circulation, and body temperature. Involvement of the 9th, 10th, and 12th cranial nerves is most important because it results in paralysis of the pharynx, tongue, and larynx, with consequent airway obstruction. Third, *bulbospinal poliomyelitis with respiratory insufficiency* refers to involvement of the respiratory muscles with coexisting bulbar paralysis.

TABLE 165-22 Common Sources of Hypoxia and Hypercapnia in Poliomyelitis

1. Cranial nerves IX to XII involved with
   a. Pharyngeal paralysis and pooling of secretions
   b. Laryngeal involvement, either spasm of laryngeal muscles or paralysis of vocal cords
   c. Lingual paralysis
   d. Tracheal accumulation of secretions from inability to cough
   e. Aspiration of vomitus
2. Vital center involvement with
   a. Inefficient, irregular respiration
   b. Cardiovascular disturbance
   c. Hyperpyrexia causing increased oxygen consumption
3. Cervical and spinal cord involvement causing paresis of the primary and accessory muscles of respiration
4. Pulmonary complications (e.g., pneumonia, atelectasis, and edema)
5. Contributory factors
   a. Panic
   b. Gastric dilation
   c. Sedation
   d. Inadequate equipment (e.g., small-bore tracheostomy tubes, unsuitable respirator settings)

From Cherry JD. Enteroviruses. In: Behrman RE, Vaughan VC, editors. *Nelson textbook of pediatrics.* 12th ed. Philadelphia, W.B. Saunders, 1983, p. 791-804.

The clinical findings resulting from involvement of the respiratory muscles are (1) an anxious expression; (2) inability to speak without frequent pauses, a situation resulting in short, jerky, "breathless" sentences that can be demonstrated by asking the child to count numbers serially; (3) increased respiratory rate; (4) movement of the alae nasi and the accessory muscles of respiration; (5) inability to cough or sniff with full depth; (6) paradoxical abdominal movements caused by diaphragmatic immobility from spasm or weakness of one or both leaves; and (7) relative immobility of the intercostal spaces, whether segmental, unilateral, or bilateral. When the arms are weak and especially when deltoid paralysis occurs, one should beware of impending respiratory paralysis because the phrenic nerve nuclei are in adjacent areas of the spinal cord. Observing the patient's capacity for thoracic breathing while the abdominal muscles are splinted manually can be performed to assess minor degrees of paresis. Light manual splinting of the thoracic cage helps in evaluating the effectiveness of diaphragmatic movement.

The clinical findings of bulbar poliomyelitis with respiratory difficulty (other than paralysis of the extraocular, facial, and masticatory muscles) include the following:

1. Nasal twang to the voice or cry as a result of palatal and pharyngeal weakness (hard consonant words such as "cookie" or "candy" bring out this condition best.
2. Inability to swallow smoothly that results in an accumulation of saliva in the pharynx and

indicates partial immobility (holding the larynx lightly and asking the patient to swallow confirms the immobility).
3. Accumulated pharyngeal secretions, which may cause irregular respiration because each inspiration must be "planned" and cannot be "subconscious" in view of the risk for aspirating; the respirations thus may appear interrupted and abnormal even to the point of falsely simulating intercostal or diaphragmatic weakness.
4. The impossibility of effective coughing, with resultant constant and fatiguing efforts to clear the throat.
5. Nasal regurgitation of saliva and fluids caused by palatal paralysis, with an inability to separate the oropharynx from the nasopharynx during swallowing.
6. Deviation of the palate, uvula, or tongue.
7. Involvement of vital centers, as manifested by an irregularity in the rate, depth, and rhythm of respiration; by cardiovascular alterations that include changes in blood pressure (especially increased), alternate flushing and mottling of the skin, and cardiac arrhythmias; and by rapid changes in body temperature.
8. Paralysis of one or both vocal cords that causes hoarseness, aphonia, and, ultimately, asphyxia unless recognized by laryngoscopy and managed by immediate tracheostomy.
9. The "rope sign," an acute angulation between the chin and larynx caused by weakness of the hyoid muscles (the hyoid bone is pulled posteriorly, thus narrowing the hypopharyngeal inlet).

Myocardial failure sometimes develops secondary to pulmonary complications or as a result of acute myocarditis. The initial manifestation of poliovirus infection on occasion can resemble that of Guillain-Barré syndrome.[1103]

Congenital Infections

Abortion. Poliomyelitis is associated with an increased incidence of abortion. Horn[459] noted 43 abortions in 325 pregnancies complicated by maternal poliomyelitis. Abortion was related directly to the severity of the maternal illness, including the degree of fever during the acute phase of illness. However, abortion also has occurred in association with mild nonparalytic poliomyelitis. Siegel and Greenberg[394] noted that fetal death occurred in 14/30 instances (46.7%) of maternal poliomyelitis during the first trimester. Kaye and associates[551] reviewed the literature in 1953 and recorded 19 abortions in 101 cases of poliomyelitis in pregnancy. In a small study in Evanston Hospital in Illinois, the abortion rate in maternal poliomyelitis was little different from the expected rate.[100]

Congenital Malformations. Although isolated instances of congenital malformation and maternal poliomyelitis have been noted, little statistical evidence supports the suggestion that polioviruses are teratogens. In their review of the literature, Kaye and colleagues[551] noted 6 anomalies in 101 infants born to mothers with poliomyelitis during pregnancy. In the reviews of Horn,[459] Bates,[58] and Siegel and Greenberg,[394] no evidence of maternal polioviral infection–induced anomalies was found. Similarly, no evidence suggests that infection with poliovirus vaccine during pregnancy causes congenital malformations.[423]

Prematurity and Stillbirth. In Horn's study[459] of 325 pregnancies, 9 infants died in utero. In each instance, the mother was critically ill with poliomyelitis. Horn[459] also noted that 45 infants weighed less than 6 lb, and 17 of them had a birth weight less than 5 lb. These low-birth-weight infants were born predominantly to mothers who had poliomyelitis early in pregnancy. In New York City, Siegel and Greenberg[394] also noted an increase in prematurity after maternal poliomyelitis infection. It was related specifically to maternal paralytic poliomyelitis.

Neonatal Infections

General. In the excellent review by Bates[58] in 1955, 58 cases of poliomyelitis in infants younger than 1 month were described. Although complete data were not available on many of the cases, 51 had paralysis, died of their disease, or both. Of the total number of infants on whom these investigators had clinical data, only one infant had nonparalytic disease. More than half the cases were secondary to maternal disease. Because other investigators have noted congenital infection without symptomatic maternal infection, infection in the mother probably was the source for an even greater percentage of the neonatal illnesses. The incubation period of neonatal poliomyelitis has not been established, and, therefore, determining how many of the babies were infected in utero is difficult. Probably, most illnesses that occurred within the first 5 days of life were congenital. Most of the neonates had symptoms of fever, anorexia or dysphagia, and listlessness. Almost half of the infants noted in this review died, and of those surviving, 48 percent had residual paralysis.

Infection Acquired In Utero. Elliott and associates[300] described an infant girl in whom "complete flaccidity" was noted at birth. This child's mother had mild paralytic poliomyelitis, with the onset of minor illness occurring 19 days before the infant's birth. Fetal movements had ceased 6 days before delivery, a finding suggesting that paralysis had occurred at this time. On examination, the baby was severely atonic; when supported under the back, she was passively opisthotonic. Respiratory efforts were abortive and were confined to the accessory muscles; laryngoscopy revealed complete flaccidity in the larynx.

Johnson and Stimson[521] reported a case in which the mother's probable abortive infection occurred 6 weeks before the birth of the baby. The baby initially was thought to be normal but apparently underwent no medical examination until the fourth day of life. At this time, the physician noted right hemiplegia. On the following day, a more complete examination revealed lateral bulging of the right side of the abdomen accompanied by crying and maintenance of the lower extremities in a frog leg position. Adduction and flexion at the hips were weak, and the knee and ankle jerks were absent. Laboratory

studies were unremarkable except for examination of CSF. It revealed 20 lymphocytes and a protein level of 169 mg/dL. During a 6-month period, this child's paralysis gradually improved and resulted in only residual weakness of the left lower extremity.

Paresis of the left arm was noted shortly after birth in another child with apparent transplacentally acquired poliomyelitis.[661] At 2 days of age, the baby was quadriplegic, but patellar reflexes were present, and the child had no respiratory or swallowing difficulties. This child had pneumonia at 3 weeks of age, but otherwise, general neurologic improvement occurred. Examination at 8 weeks of age revealed bilateral atrophy of the shoulder girdle muscles. The CSF from this patient had 63 leukocytes/mm^3, 29 percent of them polymorphonuclear cells, and a protein concentration of 128 mg/dL.

All three of the infants just discussed apparently were infected in utero several days before birth. Their symptoms were exclusively neurologic; fever, irritability, and vomiting did not occur.

Postnatally Acquired Infection. In contrast to infections acquired in utero, those acquired postnatally are more typical of classic poliomyelitis. Shelokov and Weinstein[937] described a child who was asymptomatic at birth. The onset of minor symptoms in the mother occurred 3 weeks before delivery, and the onset of major symptoms occurred 1 day before delivery. On the sixth day of life, the infant suddenly became ill with watery diarrhea. He looked grayish and pale. On the following day, he was irritable, lethargic, and limp and had a temperature of 38° C (100.4° F). Mild opisthotonos and weakness of both lower extremities developed. He was responsive to sound, light, and touch. The CSF had an elevated protein level and an increased number of leukocytes. His condition worsened during a total period of 3 days, and then gradual improvement began. At 1 year of age, he had severe residual paralysis of the right leg and moderate weakness in the left leg.

Baskin and associates[56] described two infants with neonatal poliomyelitis. The first child, whose mother had severe poliomyelitis at the time of delivery, was well for 3 days and then had a temperature of 38.3° C (100.9° F). On the fifth day of life, the boy became listless and cyanotic. Examination of CSF revealed a protein level of 300 mg/dL and 108 leukocytes/mm^3. His condition worsened, and extreme flaccidity, irregular respiration, and progressive cyanosis developed; he died on the seventh day of life. The second infant was a boy who was well until he was 8 days old but then became listless, with a temperature of 38.38° C (101.08° F). During the next 5 days, flaccid quadriplegia developed, as did irregular, rapid, and shallow respirations and an inability to swallow. The child died on the 14th day of life. Acute poliomyelitis had developed in his mother 6 days before the onset of his symptoms.

Abramson and colleagues[4] reported four children with neonatal poliomyelitis, two of whom died. In three of the children, the illnesses were typical of acute poliomyelitis in older children. The other child died at 13 days of age with generalized paralysis. The onset of his illness was difficult to define, and he was never febrile. Bates[58] described infants with acute poliomyelitis and clinical illnesses similar to those that occur in older persons.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Clinical Diagnosis

Clinical differentiation of enteroviral disease frequently is thought to be impossible. Although treatable bacterial illnesses always should be considered and treated first, also true is that when all the circumstances of a particular illness are considered, enteroviral diseases can be suspected on clinical grounds. The most important factors in clinical diagnosis are the season of the year, geographic location, exposure, incubation period, and clinical symptoms.

In temperate climates, prevalence of EVs is distinctly seasonal, so disease usually is seen in the summer and fall. Enteroviral disease is less likely to occur in the winter. In the tropics, EVs are prevalent throughout the year, and the season, therefore, is not diagnostically helpful.

As with all infectious illnesses, knowledge of exposure and incubation time is important. A careful history of maternal illness is critical in neonatal disease. For example, nonspecific, mild febrile illness in a mother that occurs in the summer and fall should warn of the possibility of severe neonatal illness. Specific findings (i.e., aseptic meningitis, pleurodynia, herpangina, pericarditis, myocarditis) should alert the clinician to enteroviral illnesses. The short incubation period of enteroviral infections should be considered.

Laboratory Diagnosis

Virus Isolation and Detection Techniques

Most viral diagnostic laboratories have facilities for the recovery of most EVs that cause illness. A three-tissue culture system that includes primary monkey kidney, a diploid, human embryonic lung fibroblast cell strain, and the RD cell line will allow the isolation of virtually all coxsackieviruses B and echoviruses and some coxsackieviruses A (e.g., coxsackieviruses A9 and A16). In a study in which Buffalo green monkey kidney cells and subpassage of primary human embryonic kidney cells were used in addition to primary monkey kidney and human diploid fibroblast (MRC-5) cells, the recovery rate of EVs was increased 11 percent.[210] For a complete diagnostic isolation spectrum, suckling mouse inoculation also should be performed.

Proper selection and handling of specimens are most important in the isolation of viruses. Enteroviral infections tend to be generalized, so collection of material from multiple sites is important; specimens should be collected from any or all of the following: nasopharynx, throat, stool, blood, urine, CSF, and any other body fluids that are available. Swabs from the nose, throat, and rectum should be placed in a carrying medium containing a small amount of protein. Hanks balanced salt solution with 2 percent agamma calf serum and antibiotics is

satisfactory. Fluid specimens should be collected in sterile vials; specimens of postmortem material are collected best in vials that contain carrying medium. In general, specimens should be refrigerated immediately after collection and during transportation to the laboratory. The specimens must not be exposed to sunlight during transportation. If an extended period will elapse before a specimen is processed in the laboratory, shipping and storing it frozen is advisable.

Contrary to popular belief, tissue culture evidence of enteroviral growth takes only a few days in many cases and less than a week in most.[392] The use of spin amplification, the shell vial technique, and monoclonal antibodies has been shown to reduce the time of detection in enteroviral cultures significantly.[586,814,935,1002] After an EV has been isolated, type identification is performed conventionally by neutralization, and this process, unfortunately, frequently takes a long time.

Nucleic acid techniques with cDNA and RNA probes have been shown to be useful for direct identification of EVs.* Most important, however, has been the development of numerous PCR techniques. Since 1990, many reports have described enteroviral, parechoviral, and SAFV PCR methods and their use in identifying viral RNA in clinical specimens.†

PCR has proved most useful for the direct identification of EVs and PeVs in the CSF of patients with meningitis.[887,912,982,993,1098] When compared with culture of CSF specimens, PCR is faster and more sensitive and the specificity is equal.

PCR also has proved useful in the identification of EVs and PeVs in blood, urine, and throat specimens.‡ Particularly impressive are the findings of Byington and associates[119] and Rittichier and associates.[867] Using PCR on specimens of blood and CSF, these investigators found that more than 25 percent of infants admitted to the hospital for suspected sepsis in 1997 had nonpolio enteroviral infections. Based on this study and the work of Andréoletti and coworkers,[18] we consider that the general workup for febrile children hospitalized for possible sepsis should include PCR for EVs and PeVs in both blood and CSF, if available. A shortcoming of PCR is that EV RNA is identified but a specific enteroviral type is not. Because of this shortcoming, we recommend that conventional culture be performed in addition to PCR. However, in the research setting, further molecular study often can identify the genotype of a causative agent from the original sample submitted for PCR assay.[567]

EV RNA also has been identified in numerous tissue specimens from patients with chronic medical conditions such as idiopathic DCM. However, as discussed earlier in the section on cardiovascular Manifestations, the possibility of a lack of specificity (false-positive results) is a concern. Polioviruses can be separated from other EVs, and poliovirus vaccine strains can be identified rapidly by PCR.[3,198,293,1095]

Serology

Except in special circumstances, the use of serologic techniques for establishing the primary diagnosis of suspected enteroviral infection is impractical. Standard serologic study depends on the demonstration of a rise in antibody titer to a specific virus as an indication of infection with that agent. Although ELISA, hemagglutination inhibition, and complement fixation take only a short time to perform, these tests can be carried out only after a second, convalescent-phase blood specimen has been collected. These tests also are impractical in searching for the cause of a specific illness in a child because of the existence of so many antigenically different EVs. As noted previously in the discussion of antigenic characteristics, group antigens can be produced that allow one to establish a serologic diagnosis by IgM EIA (enzyme immunoassay) and complement fixation, but these tests lack specificity.[899,905,990]

In the evaluation of a patient with a suspected enteroviral infection, serum should be collected as soon as possible after the onset of illness and then again 2 to 4 weeks later. This serum should be stored frozen. In most clinical situations, performing serologic tests on the collected serum is not necessary because demonstration of a rise in antibody titer in the serum of an infant from whom a specific virus has been isolated from a body fluid obviously is superfluous. However, collected serum can be useful diagnostically if the prevalence of specific EVs in a community is known. In this situation, looking for antibody titer changes to a selected number of viral types is relatively easy. Faster diagnosis can be made with a single serum sample if a search for specific IgM enteroviral antibody is made.*

Unfortunately, no EV IgM antibody tests are commercially available in the United States. Commercial laboratories offer enteroviral complement fixation antibody panels. However, these tests are expensive, and their results in the clinical setting almost always are meaningless unless acute-phase and convalescent-phase sera are analyzed.

Histology

Enteroviral infections have no specific histologic findings such as those seen in cytomegalovirus or HSV infection. However, tissues can be examined for specific enteroviral antigens by immunofluorescence and for RNA by PCR.[116,155,675]

Differential Diagnosis

The differential diagnosis of enteroviral infection depends on the clinical manifestations. In general, the most important considerations relate to bacterial diseases such as those commonly associated with pharyngitis, pneumonia, pericarditis, meningitis, and septicemia. Other viruses must be considered with upper respiratory tract illnesses,

gastrointestinal infections, rashes, encephalitis, and neonatal illness.

Paralytic poliomyelitis usually presents no diagnostic problem in the presence of an outbreak, but sporadic cases are another matter, especially in countries such as the United States, where the disease (except for the vaccine-associated form) has disappeared and many pediatricians have never seen a case. Rarely, other EVs have been shown to cause paralytic syndromes that are indistinguishable from poliomyelitis.

Several other diseases must be considered in the differential diagnosis of sporadic cases of paralytic illness. Guillain-Barré syndrome is the most common and difficult differential diagnostic problem. Fever, headache, and meningeal signs usually occur less commonly in Guillain-Barré syndrome; the paralysis characteristically is symmetric, and sensory changes are common findings. Also in Guillain-Barré syndrome, the CSF contains few cells but a significant elevation in protein concentration. Other illnesses confused with paralytic poliomyelitis include peripheral neuritis (postinjection, toxic, herpes zoster), arboviral infection, rabies, tetanus, botulism, and tick paralysis.

TREATMENT

Specific Therapy

No specific therapy for any enteroviral infection is approved for use in the United States. In severe, catastrophic, and generalized neonatal infection, in all probability the baby received no specific antibody for the particular virus from the mother. In this situation, administering immunoglobulin to the infant probably is advisable because high titers of neutralizing antibody to many EVs frequently are present in immunoglobulin.[213,248] Little evidence supports the claim that this therapy is beneficial; however, it can be expected to stop further organ seeding secondary to continued viremia. Intravenous or intraventricular injection of immunoglobulin with IVIG and administration of hyperimmune plasma have been useful on some occasions and not others in the treatment of enteroviral infection in patients with agammaglobulinemia.*

Abzug and associates[8] performed a small but controlled study in which nine EV-infected neonates received IVIG and seven similarly infected infants received supportive care. In this study, no significant difference was found in clinical scores, antibody values, or the magnitude of viremia and viruria in those treated versus control infants. However, five infants received IVIG with a high neutralizing antibody titer (>1:800) to their individual viral isolates, and they experienced faster cessation of viremia and viruria. A neonate with disseminated echovirus 11 infection and hepatitis, pneumonitis, meningitis, DIC, decreased renal function, and anemia who survived after receiving a large dose of IVIG and supportive care was described.[528] Administering IVIG to older children with life-threatening enteroviral infection also seems reasonable. A specific recommended dosage is unknown, but 400 mg/kg/day for 4 days or 2 g/kg in one dose has been used.

Jantausch and associates[512] reported an infant with a disseminated echovirus 11 infection who survived after receiving maternal plasma transfusions. A neonate with fulminant echovirus 11 infection survived after undergoing orthotopic liver transplantation.[219]

The antiviral drug pleconaril offers promise for the treatment of enteroviral infections.* This drug is a novel compound that integrates into the capsid of EVs. It prevents virus attachment to cellular receptors and the uncoating and subsequent release of viral RNA into the host cell. In a double-blinded, placebo-controlled study of 39 patients with enteroviral meningitis, a statistically significant shortening of duration of disease was noted—from 9.5 days in controls to 4.0 days in drug recipients.[886] Pleconaril also has been used on a compassionate-release basis for the treatment of patients with life-threatening infection.[59,112,883] The following categories of enteroviral illness have been treated: chronic meningoencephalitis in patients with agammaglobulinemia or hypogammaglobulinemia, neonatal sepsis, myocarditis, poliomyelitis (wild-type or vaccine associated), and encephalitis, as well as in bone marrow transplant recipients. Although these treatment studies have not had control arms, favorable clinical responses have been observed in 26/50 treated patients, including 12/18 patients with chronic meningoencephalitis. Pleconaril is not available in the United States.

In severe illnesses such as neonatal myocarditis or encephalitis, a frequent temptation is to administer corticosteroids. Although some workers have thought that this therapy is beneficial in treating coxsackieviral myocarditis, we recommend that corticosteroids not be given during acute enteroviral infection. The deleterious effects of these agents in coxsackieviral infection of mice are particularly persuasive factors in this opinion.[96,576] Immunosuppressive therapy for myocarditis of unknown origin with prednisone and cyclosporine or azathioprine was evaluated in a controlled trial of 111 adults, but no beneficial effect was observed.[678]

Because the possibility of bacterial sepsis cannot be ruled out in many instances of enteroviral infection, antibiotics frequently should be administered for the most likely potential pathogens. Care in the selection and administration of antibiotics is urged so that drug toxicity is not added to the problems of the patient.

Nonspecific Therapy

Mild, Nonspecific Febrile Illness

In patients in whom fever is the only symptom, careful observation is important. Many patients who eventually become severely ill initially have 2 to 3 days of fever without other localized findings. Care should be taken to administer adequate fluids to febrile infants, and excessive elevation of temperature should be prevented if possible.

Myocarditis

Myocarditis has no specific therapy. However, congestive heart failure and arrhythmias occur, and they should be treated by the usual methods. In administering digitalis to patients with enteroviral myocarditis, paying careful attention to the initial dosage is most important because the heart often is extremely sensitive; frequently, only small amounts of digoxin are necessary.

Meningoencephalitis

In patients with meningoencephalitis, seizures, cerebral edema, and disturbances in fluid and electrolyte balance all occur frequently and respond to treatment. Seizures are treated best with phenobarbital, phenytoin, or lorazepam. Cerebral edema can be treated with urea, mannitol, or large doses of corticosteroids. As noted, the use of corticosteroids in patients with active enteroviral infection seems unwise because the local benefit may be outweighed by the overall deleterious effects. Fluids should be monitored closely, and serum electrolyte levels should be determined frequently because inappropriate antidiuretic hormone secretion is a common occurrence.

Poliomyelitis

The broad principles of management are to allay fear, minimize the ensuing skeletal deformities, anticipate and meet complications in addition to the neuromusculoskeletal ones, and prepare the child and family for the prolonged treatment that may be required and for permanent disability when it seems likely. Patients with the nonparalytic and mildly paralytic forms of the disease may be treated at home.

Most patients with paralytic poliomyelitis require hospitalization. A calm atmosphere is desired. Suitable body alignment is necessary to avoid excessive skeletal deformity. A neutral position with the feet at a right angle, knees slightly flexed, and hips and spine straight is achieved by the use of boards, sandbags, and, occasionally, light splint shells. Active and passive motion is indicated as soon as the pain has disappeared. The orthopedist and physiatrist should see these patients as early in the illness as possible and should assume responsibility before fixed deformities develop.

Management of pure bulbar poliomyelitis consists essentially of maintaining the airway and avoiding all risks for inhalation of saliva, food, or vomitus. Gravity drainage of accumulated secretions is favored by the head-low (foot of the bed elevated 20 to 25 degrees), prone position with the face to one side. Aspirators with rigid or semirigid tips are preferred for direct oral and pharyngeal use, and soft flexible catheters may be used for nasopharyngeal aspiration. Fluid and electrolyte balance is maintained best by intravenous infusion because tube or oral feeding in the first few days may incite vomiting. After the initial few days, sips of sterile water may be given from a spoon, with increments as indicated by the child's ability to swallow. In addition to close observation for respiratory insufficiency, blood pressure should be recorded at least twice daily. Hypertension is not an uncommon occurrence and occasionally leads to hypertensive encephalopathy. Patients with pure bulbar poliomyelitis may require tracheostomy because of paralysis of the vocal cords or constriction of the hypopharynx. Most patients with pure bulbar poliomyelitis who recover have little residual impairment; some patients exhibit mild dysphagia and occasional vocal fatigue with slurring of speech.

Impaired ventilation must be recognized early; mounting anxiety, restlessness, and fatigue are early indications for prompt intervention. Tracheostomy is indicated for some patients with pure bulbar poliomyelitis, spinal respiratory muscle paralysis, and bulbospinal paralysis. Unlike other patients on whom tracheostomy is performed, these patients generally are unable to cough, sometimes for many months. Frequent and swift endotracheal aspiration under aseptic conditions is necessary. Mechanical ventilation often is needed. Patients are fully conscious and aware; terrifying procedures are performed best with an outward atmosphere of calm. Explaining the procedure and having the parents on hand may be helpful. A reduction in thoracic compliance occurs early, and higher than expected pressure gradients may be required to achieve adequate ventilation. Weaning a patient from dependency on respiratory assistance is a torturous process, as is total musculoskeletal rehabilitation. Motivation of the patient and the team of personnel is paramount.

PROGNOSIS

The prognosis for nonpolio enteroviral infections is excellent in most instances. Virtually all morbidity and mortality are related to cardiac and neurologic disease in older children and to these diseases in addition to general disseminated infection with hepatitis in neonates.

The prognosis for poliomyelitis varies with the degree of muscle involvement. In patients with mild muscle weakness, complete recovery is the rule. If paralysis is present, recovery of muscle function continues for a period of approximately 18 months to 2 years. By 3 months, approximately 60 percent of the ultimate improvement has been achieved, and by 6 months, 80 percent. The final result depends on the extent and localization of nerve cell damage.

Respiratory failure is responsible for most of the deaths in paralytic poliomyelitis. With the many improvements in techniques for handling this complication, the overall mortality rate has been reduced to approximately 4 percent; with the bulbar form and in adults, it still may be as high as 10 percent.

Occasionally, new neuromuscular symptoms develop later in life in patients who have had paralytic poliomyelitis.* Although the cause of this late-onset weakness and muscle atrophy (postpolio syndrome) is not understood completely, it most likely is the result of routine attrition of anterior horn cells associated with aging rather than persistent neural infection with polioviruses. However,

*References 130, 250, 251, 523, 845, 994, 1077, 1076.

specific immunopathologic mechanisms possibly play a role in some instances.[371]

Leparc-Goffart and associates[625] presented data suggesting the presence of poliovirus-specific genomic sequences in the CSF of patients with postpolio syndrome. However, Muir and colleagues,[739] who performed similar studies, found no association of chronic neurologic disease with the presence of enteroviral RNA in CSF.

PREVENTION

Nonpolio Enteroviral Infections

Attenuated and inactivated viral vaccines for EVs other than polioviruses are not available. However, if a virulent enteroviral type were to emerge, a specific vaccine for active immunization probably could be developed. It would seem that EV 71 would qualify for vaccine development and use in the Asian-Pacific region. In this light, several inactivated vaccines are in various studies of development (see http://clinicaltrials.gov/ct2/results?term=enterovirus+71).

Passive protection with IVIG may be useful in preventing disease. In practice, however, it would seem worthwhile only for sudden and virulent nursery outbreaks. For example, if several cases of myocarditis occurred in a nursery, administering IVIG to all babies in the nursery would seem reasonable. Pooled human immunoglobulin in most instances can be expected to contain antibodies against coxsackieviruses B1, B2, B3, B4, and B5, as well as several coxsackieviruses A and echoviruses.[248] Therefore, this procedure would offer protection to infants without transplacentally acquired specific antibody who had not yet become infected. Immune serum was useful in the management of three nursery enteroviral outbreaks.[128,744,810]

Polioviral Infections

In the United States, the total annual number of paralytic cases fell from an average of 16,000 in the 5 years before the introduction of vaccine to approximately 10 cases per year between 1980 and 1984. The experience in 1979, however, when 26 paralytic cases were reported, served as a reminder that virulent polioviruses still could surface in susceptible persons.[134,135] Most of the 1979 cases occurred in Pennsylvania and several other states in Amish population groups who had not been immunized. A similar epidemic in Connecticut in 1972 involved a pocket of unimmunized students in a Christian Science school.[131] These outbreaks reflected the reality that poliomyelitis was still occurring in many parts of the world. The possibility of the introduction of virulent strains was ever present, and only through continued and extensive immunization programs could the disease be prevented from reappearing in epidemic form.[461]

The remarkable overall record of the decline in paralytic poliomyelitis in the United States was a result of the development and use of two effective vaccines.[461] Inactivated poliovirus vaccine, the first to be licensed, was used extensively beginning in 1955 and considerably reduced the incidence of the disease, although epidemics continued to occur. Live-attenuated oral poliovirus vaccine, licensed in 1961 and 1962, subsequently was recommended as the method of choice in the United States based on its superiority in terms of immunogenic capacity, ability to induce local IgA antibody in the oropharynx and intestinal tract and thus provide greater resistance to reinfection, and ease of administration. Oral poliovirus vaccine gradually supplanted inactivated poliovirus vaccine, and between 1973 and 1978, it was the only vaccine available. Its extraordinary effectiveness at that time, despite reaching only 65 percent of children younger than 5 years of age with the recommended three doses, suggested that the capacity of the attenuated strains to spread contributed to a much higher immunization rate than was indicated by vaccination statistics. The potential impact of such spread on the immunity of the population was illustrated by the observations of Fox and Hall,[331] who conducted long-term virologic surveillance of middle-income families in Seattle. Polioviruses (vaccine strains) accounted for 50 percent of the 2937 viral isolates from healthy children, their parents, and others in the community. In an analysis of 611 of the poliovirus isolates, researchers found that 75.6 percent were from vaccinees, 10.5 percent were from vaccinee contacts, and 14 percent were from persons without recent known contact with vaccine or a vaccinee. These findings provided a vivid picture of the pervasiveness of the attenuated strains and their continuous circulation in the population. This feature also was supported by the almost invariable recovery of polioviruses from weekly samples of sewage that were collected throughout the year, in the early vaccine era, in urban communities.[463]

Despite its striking success, the oral vaccine had some problems. One was greatly reduced seroconversion rates when the vaccine was given to children living in the tropics: as few as 50 percent had satisfactory responses, in contrast to the more than 95 percent response rate in the United States and similar countries.[274,706] Viral interference from other EVs played some role, and the presence of an inhibitory substance in the oropharynx that prevented significant multiplication of the vaccine strains also was involved. The seroconversion problem was lessened by using pulse immunization programs.[518,896] For example, the strategy of national annual vaccination days twice per year, 2 months apart, has been successful in developing countries.

Another problem with oral poliovirus vaccine—and the major problem in the United States—was the occurrence of a small number of vaccine-associated cases of poliomyelitis.[461,706] The immunogenic effectiveness of the vaccine depends on multiplication of the attenuated strains in the intestinal tract. Because no poliovirus strain is completely stable, the progeny of vaccine strains underwent a certain degree of mutation, which rarely resulted in increased virulence and vaccine-associated cases in recipients and their contacts, most often their parents.

Since 1980, no indigenous cases of wild poliovirus disease have occurred in the United States.[141,965] From 1980 to 1989, 80 cases of vaccine-associated paralytic poliomyelitis and 5 cases of imported disease were

reported. The overall rate of vaccine-associated paralytic poliomyelitis was 1 case per 2.5 million doses of distributed vaccine; the risk for recipients was 1 case per 6.8 million doses, and for household contacts it was 1 case per 6.4 million doses. Of the 80 cases, 30 occurred in vaccinees, 32 occurred in household contacts, 4 were community acquired, and 14 occurred in immunologically abnormal persons.

Further analysis revealed that the risk associated with the first dose of vaccine was 1 case per 700,000 doses, but it was only 1 case per 6.9 million for subsequent doses; for vaccine recipients, the calculated risks were 1 case per 1.4 million initial doses and 1 case per 41.5 million subsequent doses. The calculated risks for contact cases were 1 case per 1.9 million initial doses of vaccine and 1 case per 13.8 million subsequent doses.

Immunodeficient children are at particular risk for acquiring vaccine-associated paralytic poliomyelitis.[132,965] From 1969 through 1976, 11 percent of vaccine-associated cases occurred in immunodeficient patients; 10/11 of these patients were children younger than 1 year of age. From 1980 to 1989, 18 percent of vaccine-associated paralytic poliomyelitis cases occurred in immunodeficient patients.[965]

Although the risks mentioned earlier were considered acceptable in view of the benefits provided, the question raised repeatedly since the 1970s was whether the United States should return to the use of inactivated poliovirus vaccine, which does not carry a risk for acquiring paralytic disease and has been highly successful in several small European countries in which more than 95 percent of the population is immunized.*

The problem was reviewed in detail by a committee of the Institute of Medicine (IOM) of the National Academy of Sciences, which reported its recommendations in April of 1977.[766] The conclusion at the time was that given the situation in the United States, in which not more than 65 percent of susceptible children were vaccinated, oral poliovirus vaccine should continue to be the principal vaccine for routine immunization. Inactivated poliovirus vaccine, conversely, should be provided for two groups: immunodeficient persons, because of their greatly enhanced risk for acquiring vaccine-associated disease after receiving the oral vaccine; and adults receiving primary immunization, because of their greater susceptibility to paralytic disease. Also suggested was that the inactivated vaccine be available as an alternative for those who prefer it. In addition, a single dose of trivalent oral poliovirus vaccine was suggested for all entrants into the seventh grade of school as a means of added protection for later years when they became parents.

In January of 1988, a panel appointed by the IOM again reviewed policy options for vaccination against poliomyelitis in the United States.[494] The IOM panel concluded that no change in policy should be recommended at that time. However, they did recommend that a new enhanced inactivated poliovirus vaccine replace the old vaccine when inactivated vaccine was indicated. They also suggested that when a new enhanced diphtheria-tetanus-pertussis inactivated poliovirus vaccine became available, a regimen of two or more doses of it followed by the oral vaccine be considered.

In 1996, the U.S. poliovirus vaccine immunization program was evaluated extensively by both the Advisory Committee on Immunization Practices (ACIP) and the Committee on Infectious Diseases of the American Academy of Pediatrics (AAP). The ACIP recommended that sequential administration of inactivated poliovirus vaccine followed by oral poliovirus vaccine be the schedule of choice in the United States (Orenstein, WA, personal communication, 1996). The schedule consisted of two doses of the inactivated vaccine at 2 and 4 months of age and two doses of the oral vaccine at 12 to 18 months and 4 to 6 years of age. Both committees indicated that schedules that include all of the doses of each vaccine also were acceptable (Hanneman RE, personal communication, 1996; Orenstein, WA, personal communication, 1996). At the present time, an all-inactivated poliovirus vaccination schedule is recommended in the United States.[17,714] It is a four-dose schedule with doses at 2 and 4 months, 6 to 18 months, and 4 to 6 years. The reader is advised to consult the recommendations of the ACIP and the AAP, as well as the manufacturers' literature, for full consideration of the contraindications and indications for poliovirus vaccines.

Routine primary poliovirus vaccination of adults older than 18 years is not conducted in the United States. However, adults at risk for exposure to wild polioviruses (i.e., laboratory workers, international travelers, health care workers) should be immunized. For the vaccination of adults, inactivated poliovirus vaccine is recommended. Patients with immunodeficiency diseases should not be given oral poliovirus vaccine; live virus also should not be used in households in which an immunodeficient person resides.

Global Eradication of Poliomyelitis

The WHO established the Expanded Program on Immunization (EPI) in 1974.[484,1047,1089] Subsequently, the use of oral poliovirus vaccine in developing countries vastly increased. In 1980 in Brazil, researchers demonstrated that mass administration with the oral vaccine on National Immunization Days (NIDs) led to a dramatic reduction in the incidence of poliomyelitis.[262] This demonstration led in 1985 to the targeted eradication of poliomyelitis from the Western Hemisphere by 1990. This campaign was successful in that the last confirmed case of paralytic poliomyelitis caused by wild poliovirus occurred in 1991 in Peru.[135] In September 1994, an international commission convened by the Pan American Health Organization certified that indigenous transmission of wild poliovirus had been interrupted in the Americas.[140]

In 1988, the World Health Assembly established the objective of global eradication of polio by 2000.[484] This program was based on four strategies recommended by the WHO: (1) maintenance of high vaccination coverage levels among children with at least three doses of oral poliovirus vaccine; (2) development of sensitive systems of epidemiologic and laboratory surveillance, including use of the standard WHO case definition (i.e., a confirmed case of poliomyelitis is defined as acute flaccid

*References 331, 346, 452, 533, 549, 742, 805, 899-902, 965.

paralysis and at least one of the following: laboratory-confirmed wild poliovirus infection, residual paralysis of 60 days, death, or no follow-up investigation at 60 days); (3) administration of supplementary doses of oral poliovirus vaccine to all young children (usually those <5 years of age) during NIDs to rapidly interrupt the transmission of poliovirus; and (4) "mopping up" vaccination campaigns, which are localized campaigns targeted at high-risk areas where wild poliovirus transmission was most likely to persist at low levels. NIDs are mass campaigns conducted over the course of a short period (i.e., days to weeks) during which two doses of oral poliovirus vaccine are administered to all children in the target age group regardless of previous vaccination history, with an interval of 4 to 6 weeks between doses.

From 1985 through 1990, worldwide routine vaccination coverage levels increased from 47 to 85 percent and stabilized at 80 to 81 percent from 1991 to 1994.[141] From 1985 through 1994, the number of cases reported annually decreased 84 percent, from 39,361 to 6241. The number of countries reporting polio cases decreased steadily from 1985 (99/196 [51%]) to 1988 (88/196 [45%]) and 1994 (51/214 [24%]). In addition, the number of countries reporting zero polio cases increased from 1985 (84 [43%]) to 1988 (104 [53%]) and 1994 (145 [68%]). The number of countries with endemic polio that conducted NIDs each year increased from 15 in 1988 to 37 in April of 1995; 24 additional countries scheduled their first NIDs for later in 1995.

At the beginning of the 21st century, NIDs had been conducted in every country in the world with endemic polio. In 1999, 7141 cases of poliomyelitis were reported worldwide. These cases occurred in 30 countries, mainly in south Asia and central Africa. By the end of 2000, fewer than 3500 cases occurred in endemic areas throughout the world, and wild-type 2 poliovirus has not been detected since October 1999.[988] At the close of 2001, the area of endemic poliomyelitis had been reduced to 10 countries, with fewer than 1000 cases reported.[754]

The global eradication program suffered a major setback in 2004 when oral poliovirus vaccine immunizations in northern Nigeria were suspended because of misinformation regarding vaccine safety.[443] After this suspension, epidemic disease caused by type 1 virus occurred throughout Nigeria and also spread directly or indirectly to 21 previously polio-free countries.[148] This epidemic, which had extensive spread, had a major negative impact on the Global Polio Eradication Initiative. During 2005, 1856 cases were reported globally, and 1000 of these cases occurred in countries with outbreaks caused by importation.

In October 2011, the Independent Monitoring Board for the Global Polio Eradication Initiative (GPEI) issued a very critical report of the GPEI.[869] This report reinvestigated the initiative, but a goal of stopping polio transmission in 2012 will not be needed. In 2011, there were four endemic countries (Afghanistan, India, Nigeria, and Pakistan).[152] In addition, reestablished transmission occurred in Angola, Chad, and the Democratic Republic of the Congo.

Much attention is being paid to the end-game strategy for global polio eradication.[226,276,277,560] Of particular concern for the future after world eradication of wild poliovirus strains is vaccine-associated paralytic poliomyelitis.[270,562,563] Other concerns are the long-term excretion of highly evolved vaccine-derived polioviruses in persons with primary immunodeficiencies and polio outbreaks associated with circulating vaccine-derived polioviruses in areas with low rates of oral poliovirus vaccine coverage. Ideally, an end-game strategy would transition to the use of inactivated poliovirus vaccine, but this strategy is not realistic in much of the developing world.

Despite the substantial progress that has been made toward global eradication of polio, several challenges remain, including (1) increasing vaccination levels in unvaccinated subpopulations; (2) preventing the reintroduction of wild poliovirus into polio-free areas by eliminating reservoirs in polio-endemic countries (particularly in the Indian subcontinent); (3) increasing the awareness of donor agencies and governments in industrialized countries of the substantial financial and humanitarian benefits of global eradication of polio, thus engendering support from unaffected countries beyond that already provided by organizations such as Rotary International; (4) encouraging all countries that remain polio endemic to make eradication of polio a high priority, including the implementation of NIDs and the initiation of acute flaccid paralysis surveillance; and (5) providing support to vaccination program managers for training to develop managerial skills for implementing and maintaining effective vaccination and surveillance programs in all countries.[141] The success of the Global Polio Eradication Initiative will depend on finding solutions to these financial, managerial, political, and technical challenges.

World events and new knowledge relating to reversion of poliovirus vaccine strains and recombination of poliovirus vaccine strains with nonpolio EVs led to the realization that decisions related to discontinuation of immunization after world eradication are exceedingly complex.[561,754,988,1082]

CHAPTER 166

RHINOVIRUSES

Robert L. Atmar • Janet A. Englund

HISTORY

The first recognized human rhinovirus (HRV) (type 1A) was isolated in monkey kidney cell culture by Pelon and associates[227] in 1954 from a recruit at Great Lakes Naval Training Center in Chicago during an outbreak of afebrile common colds in his training company. Independently, Price and colleagues[237] reported the isolation of an antigenically identical virus from nurses and children with colds. In 1963, the HRVs were so named because of their association with illnesses of the nasal passages.[282]

Before these actual virus isolations, evidence suggested that viruses cause the common cold. Despite indications that some coldlike illnesses could be complicated by bacterial infections,[75,292] bacteria-free nasal filtrates from persons with apparent symptomatic respiratory tract infections clearly were able to initiate these illnesses. Kruse,[179] in 1914, first demonstrated transmission with apparently sterile filtrates, and his results were confirmed in the late 1920s in a series of experiments in humans and chimpanzees by Dochez and associates.[75] In the 1930s, workers from this latter laboratory reported growth of the agent in tissue culture and embryonated eggs, but their results were not confirmed.[5] In the 1940s and 1950s, Andrewes and colleagues[6] at the Common Cold Unit in Salisbury, England, and Dingle and the members of the U.S. Armed Forces Commission on Acute Respiratory Diseases were able to transmit colds from person to person with apparently sterile filtrates.[54] Jackson and colleagues[158] performed similar experiments in Chicago and also demonstrated immunity. In 1953, the Salisbury researchers reported isolation of an agent, DC, in serially passaged filtrates of tubed tissue cultures of human embryonic lungs; the virus was detected by its ability to produce colds in humans. Although these results could not be substantiated at the time, a virus *was* present; in 1968, the DC filtrates were found to contain HRV-9.[5,56]

The next major advance in growing common cold viruses took place in the late 1950s in Salisbury. Tyrrell and Parsons[283] inoculated human embryonic kidney cells with nasal filtrates and incubated the cultures under conditions simulating those of the nasal passages (e.g., 33° C, neutral pH, and in a roller drum for aeration). Six distinct types of HRVs (types 1B to 6)[61] were isolated by observing cytopathic effects.[270] Shortly thereafter, Hamparian and coworkers[61,132,173] isolated 18 HRVs (types 7 to 12 and 18 to 29) by using a semi-continuous diploid cell strain obtained by Hayflick and Moorhead[139] from human fetal lung cultures. The use of Hayflick's cell lines greatly accelerated the isolation and characterization of "new" HRVs, leading to the identification of 100 serotypes.[131] More remain untyped, but the number of additional cultivable serotypes seems limited.[131,170,212]

The use of molecular methods for the sensitive detection of rhinoviruses, beginning in the 1990s, further revolutionized the field by enhanced detection and typing of rhinoviruses in the clinical setting.[126,182,193,228] In 2006, nonculturable rhinoviruses were further expanded by the detection of a wider diversity of recognized rhinoviruses associated with respiratory illness, including a new species (clade C).[9,31,182] At least 49 new types have been identified by sequencing methods.[201] In the past decade, the contribution of HRVs to disease in children, hospitalized patients, and immunocompromised patients has been increasingly appreciated with the widespread application of sensitive and more rapid molecular methods in research and clinical practice. These new detection methods have clearly demonstrated that although the HRVs are

associated primarily with mild upper respiratory tract disease, they also may be involved in bronchitis, sinusitis, and, on occasion, pneumonia in all age groups. These viruses seem to be precipitants of "infectious asthma" attacks. HRVs cause 30 to 50 percent of all acute respiratory illnesses.[61,99]

THE ORGANISM

Rhinoviruses are a member of the *Enterovirus* genus in the family *Picornaviridae*.[176] Other members of the *Enterovirus* genus include polioviruses, coxsackieviruses, and echoviruses. Like the other picornaviruses, the HRVs are small (30 nm), nonenveloped (therefore resistant to lipid solvents such as ether and chloroform), and icosahedral (20-sided, hexagonal in cross section), with a genome consisting of single-stranded RNA (molecular weight, 2.5×10^6 daltons) approximately 7200 nucleotides long.[176] A picornavirus can be thought of as an RNA genome surrounded by a 20-sided protein coat (the capsid) (Fig. 166-1). The RNA alone is infectious and can serve as a messenger.

HRVs previously were distinguished from classic enteroviruses by being rendered noninfectious at an acidity lower than pH 5 and by their higher buoyant density in cesium chloride.[122] HRVs are subdivided based on various virus characteristics as follows: (1) into three species (HRV A, HRV B, and HRV C) based on genomic sequence analysis; (2) into three groups based on receptor usage (see later); (3) into two groups based on susceptibility to capsid-binding antiviral agents; and (4) into more than 100 serotypes, as described earlier.[254] Currently, polymerase chain reaction (PCR) assays are typically used to distinguish other enterovirus species from HRVs.[192]

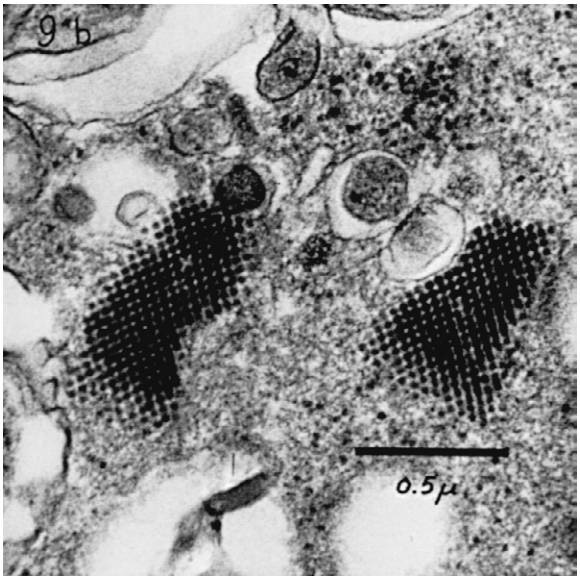

FIGURE 166-1 ■ Rhinovirus type 2 in human fetal lung cells. Note the hexagonal virus crystals closely packed in a rectangular lattice (×40,000). (From Kawana R, Matsumoto I. Electron microscopic study of rhinovirus replication in human fetal lung cells. *Jpn J Microbiol* 1971;**15**:207-17.)

The genomes of most culturable HRV serotypes have been sequenced completely.[223] Within an HRV species, a 61 to 98 percent pairwise nucleotide sequence identity of the VP1 gene exists among the different serotypes, whereas between HRV serotypes the pairwise nucleotide sequence identity for this gene is 46 to 55 percent.[181] HRV-87 has greater sequence homology to the *Enterovirus D* species (EV-68 and EV-70) than to other HRVs and has been reclassified into the *Enterovirus D* species.[28]

Structure of the Virion

The virion is composed of 60 copies of each of four structural proteins: VP1, VP2, VP3, and VP4. Knowledge of the structure of the HRVs is based on the determination of the capsid structures in atomic detail for five serotypes, HRV-1A, HRV-2, HRV-3, HRV-14, and HRV-16.* The thin (5-nm) protein capsid has an undulating exterior marked by 12 vertices (the icosahedral fivefold axis) equally spaced over the surface. Surrounding these vertices is a steep (2.5-nm deep), narrow canyon. VP1, VP2, and VP3 are exposed on the surface of the virion, whereas VP4 is buried within the capsid.

A pocket of unknown function whose walls are lined by 17 amino acids that vary with each HRV type has been found at the base of the canyon.[7] Various organic molecules have been determined to bind in this pocket; when these molecules are bound, either the virus is prevented from uncoating (necessary to release viral RNA for its translation to viral protein) or the cell receptor is prevented from docking in the canyon.[100,231] Numerous drugs made by several different drug companies in the United States, Europe, and Japan have been developed to exploit the anti-picornavirus potentialities of this pocket, and the sensitivity of the HRVs to these drugs has been used as an additional means of classifying the HRVs (into inhibitor groups A and B).[7,8] One group of these drugs, the WIN compounds synthesized by Sterling-Winthrop, has had wide scientific exposure; however, clinical trials have been discouraging.[273,275] One disadvantage of these compounds is that the various HRV serotypes vary widely in sensitivity to these organic molecules.[7] Another problem has been failure to attain effective concentrations of drug at the site of infection.

Virus Life Cycle

The first step in the virus life cycle is binding to its cellular receptor. There are only two different receptor binding sites for the culturable HRV serotypes: 90 serotypes bind to intercellular adhesion molecule-1 (ICAM-1, the major receptor group), and 10 other serotypes bind to members of the low-density lipoprotein receptor family (LDL-R, the minor receptor group.[1,115,285] The receptor(s) of clade C viruses have not been identified for clade C rhinoviruses because members of this species are currently noncultivable.

ICAM-1 binds to the base of the canyon of HRVs in the major receptor group.[247,249,285] Virus-neutralizing

*References 10, 174, 247, 248, 288, 304.

antibody prevents virus attachment to cells by adhering to serospecific sites and blocking the cell receptor from access to its binding site at the canyon base. These antibody sites may directly overlap ICAM-1–binding sites, or they may be separate from the ICAM-1–binding sites but at a point sufficiently close to allow the binding site to be blocked by steric hindrance.[46,261] Binding of the major receptor group HRVs to ICAM-1 leads to destabilization of the virus capsid and uncoating of the viral RNA.[116]

The LDL-R family binds to a different site for the minor receptor group of HRVs than that recognized by ICAM-1. The binding site for these HRVs is the small, star-shaped dome above the canyon on the icosahedral fivefold axis. Attachment of minor receptor group viruses to LDL-R does not lead to virus uncoating, in contrast to what is seen with binding of major receptor group HRVs to ICAM-1. Instead, internalization into acidic endosomal compartments is required for uncoating of minor receptor group HRVs.[144]

Replication of the HRVs is similar to that of the enteroviruses.[243] After attachment to the cellular receptor and endocytosis of the virus, RNA is released into the cytoplasm. Genomic viral RNA functions as messenger RNA and attaches to ribosomes, which stimulates its translation by host enzymes into a single long polyprotein. This polyprotein is cleaved by viral proteases to yield viral RNA polymerase, capsid proteins, proteases, and proteins to halt the synthesis of host proteins and other products. Under laboratory conditions, infectious virus first is formed after approximately 2 hours and reaches a maximum of approximately 1000 infectious particles per cell at approximately 7 hours. Infectious virus, however, comprises a minority of the virus-like particles formed; only approximately 1 in 200 is a complete virus capable of replicating in cell culture. All viral replication occurs in the cytoplasm, and viruses are released by cell lysis in a process involving apoptosis.[66,243]

Host Range

Animals

Rhinoviruses have been isolated from natural infections in only chimpanzees and humans.[176] Chimpanzee infections are subclinical. A natural, subclinical outbreak of HRV-31 in chimpanzees was reported in a primate center.[69,70]

Many attempts have been made to infect a wide variety of animals with HRVs. In addition to the chimpanzee, the gibbon has been susceptible, but it is not reliably so.[70] Mice do not naturally express ICAM-1, the major receptor, and are not infected by these viruses. The block can be overcome by engineering mouse cells to express ICAM-1, a finding that recently led to the development of a transgenic mouse model for HRV infection.[25,134,280] Mice also can be infected by HRVs that express the minor receptor.[25,302] Mutations in viral nonstructural proteins can improve the replication efficiency of mouse-adapted rhinoviruses in both major and minor receptor groups.[134,302] Equine and bovine "rhinoviruses" have been described, but these viruses belong to different picornavirus genera.[176]

Cell and Tissue Cultures

The spectrum of tissue culture cells infected by HRVs also is narrow.[58,183] For initial isolation, human embryonic diploid cells generally are used (Fig. 166-2), although for some HRV types, an especially sensitive strain[55] of a continuous cell line, HeLa, serves as well or better.[58,183] Some HRVs grow only in human organ cultures and, as noted earlier, some only in living humans.[183]

The first HRV (HRV-1A) was propagated in primary cell culture from primate kidneys (rhesus monkey cell cultures are used most commonly); surprisingly, chimpanzee kidney cell cultures do not propagate HRVs.[67] However, most HRVs propagate on original isolation only in cells of human origin, and they are called H strains; others also can be isolated in monkey kidney cell cultures and are called M strains. After laboratory propagation, all HRVs seem adaptable to the HRV-sensitive HeLa cell strain.[55] HeLa-grown HRVs attain much higher titers than those in the primary human diploid cells used for initial isolation.

Antigenic Properties

A prominent characteristic of HRV is its great antigenic diversity; more than 100 cultivable serotypes exist.[131] Evidence has shown, however, that the number of additional serotypes of cultivable strains may be limited.[99,131,170,212] Certain serotypes cross react, but little evidence indicates that this cross reaction could be exploited in vaccination.[57,97,210] Genetic analyses suggest that close to 50 additional serotypes may exist among clade C HRVs.[201,258]

HRVs often are poor antigens. Significant (fourfold or greater) increases in serum antibody may not develop in as many as 50 percent of patients from whom HRVs are isolated, and the levels attained often are low.[97-99]

HRVs may be undergoing continuous antigenic change.[210] One mechanism that may lead to the emergence of new strains is recombination. The sequencing of complete viral genomes has identified a number of probable recombination events between different virus serotypes. The recombinants then diverged further from the parental strains and became new serotypes.[223] Sufficiently marked antigenic variation has been found for HRV-22 and HRV-51 to interfere with their typing.[256,266]

EPIDEMIOLOGY

HRVs cause infection with a worldwide distribution, and large epidemiologic studies have consistently identified HRVs as the most common cause of viral respiratory disease. For example, two population-based studies in Roehampton, England[148] and Tecumseh, Michigan,[213] both found HRVs more frequently than other respiratory viruses, with HRVs causing 26.3 percent and 38.1 percent, respectively, of all respiratory illnesses. More recent studies of acute respiratory illness in children also identified HRVs most commonly.[9,180] Infection is more common in children than in adults. The annual incidence in children is approximately one infection per year, although

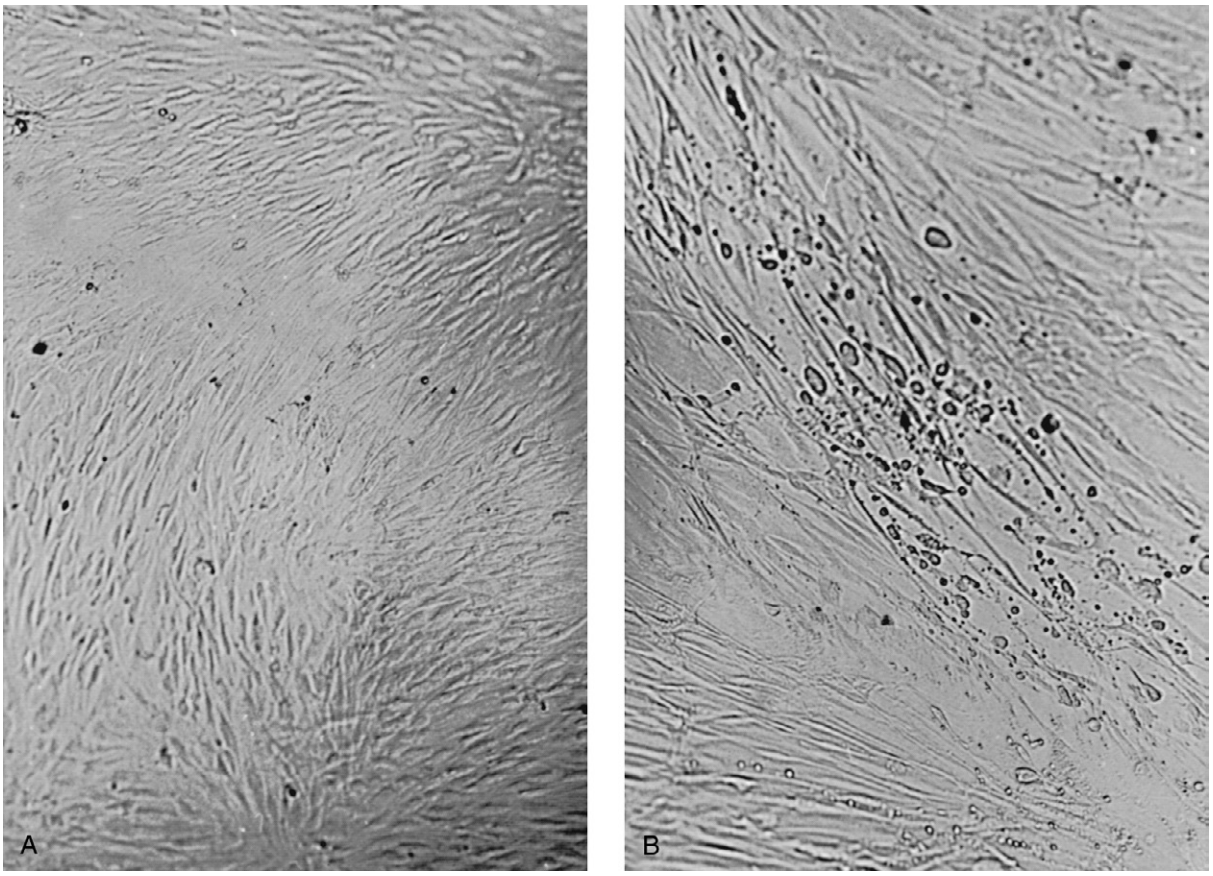

FIGURE 166-2 ■ Rhinovirus type 16 infection. **A,** Normal human diploid (fetal tonsil) cell sheet. **B,** Cell sheet infected for 2 days with rhinovirus type 16. The rounded and misshapen cells are characteristic. (Courtesy Dr. David M. Warshauer, University of Wisconsin, Madison, WI.)

one study reported an incidence as high as six infections per year.[298]

Seasonal Distribution

HRV causes infections year round, although there are seasonal peaks of occurrence.* During the usual September through May "cold season," HRV infections often are predominant at both ends, early fall and middle-to-late spring (Fig. 166-3). They also are important causes of summer colds. This seasonal pattern seems general because similar findings have been reported from families in Charlottesville, Virginia, Seattle, Washington, and elsewhere.† In the Southern Hemisphere, a similar seasonal pattern occurs, but during opposing months.[164]

Cycling and Circulation of Individual Rhinovirus Types

Several HRV serotypes usually circulate simultaneously within a community,[133] frequently coincident with other respiratory viruses.[68,148,213] For example, in a study of 24 neighboring families in Madison, Wisconsin (Eagle Heights Village), 14 different HRV types in addition to several nontypeable HRVs were found during the two academic years 1963 to 1965. Only a single type (HRV-15) was found both years. The other common respiratory viruses also were present. In virus surveillance studies performed in families in Seattle and Tecumseh a few "common" serotypes were found to be more prevalent in a given respiratory season and to be identified in subsequent respiratory seasons.[99,212] However, most individual HRV types do not repeat within a population from year to year.

Although several HRV types usually circulate concurrently, all types present are not equal in prevalence. In a Chicago nursery school study,[26] 14 different serotypes were isolated during the academic year 1962 to 1963, but 10 of the serotypes did not spread at all. Only 3 types disseminated widely, and they infected more than 40 percent of the children. Similarly, in the 1963 to 1965 Eagle Heights Village study, 14 HRV types were isolated, but only 3 types (HRV-43, HRV-51, and HRV-55) were "spreaders." Similar patterns of serologic prevalence were reported from laboratories in Tecumseh,[213] New York City, Seattle,[98,99] and Charlottesville.[142]

Predominating Rhinovirus Types

Although the pattern of predominating HRV types within a circumscribed population and a defined time frame

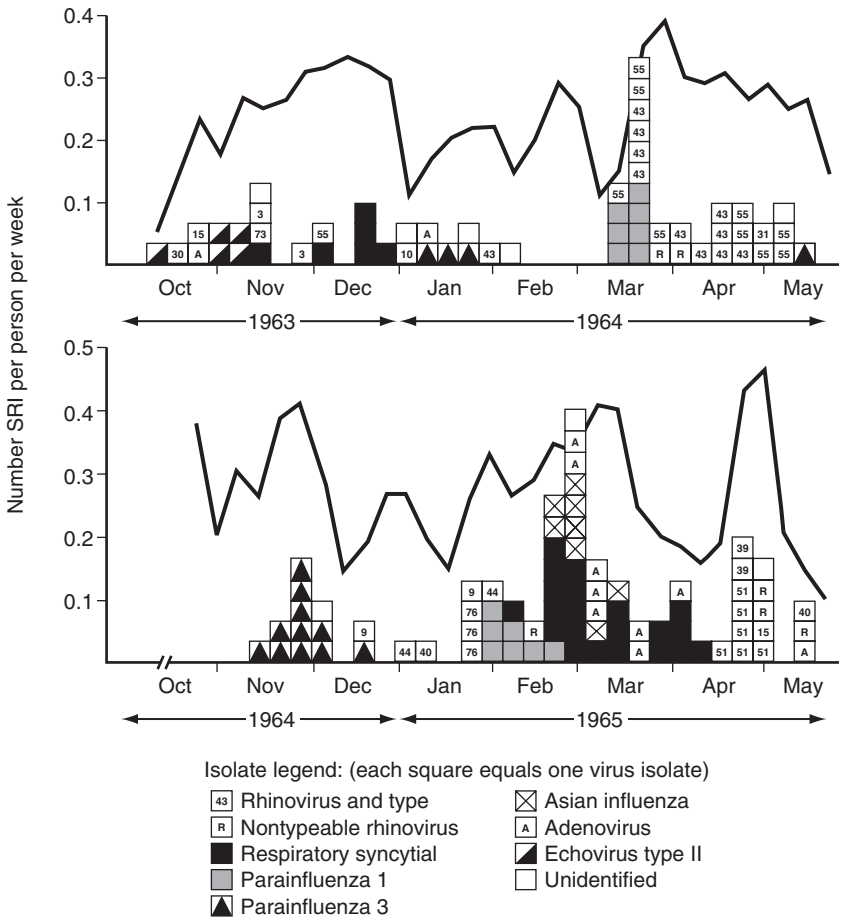

FIGURE 166-3 ■ Rhinoviruses and other respiratory viruses associated with symptomatic respiratory infection. This study included three neighboring apartment buildings in Eagle Heights, a University of Wisconsin housing village in Madison, Wisconsin (24 to 26 families, ≈100 persons), from 1963 to 1965.

seem to be well established, a predominance of serotypes over large geographic areas or over many years does not seem to occur. This phenomenon was studied exhaustively in widely separated locations and over many years: the Gulf South from 1962 to 1970, Tecumseh from 1966 to 1971 and from 1976 to 1981, and Seattle from 1965 to 1969 and from 1975 to 1979.[98,99,210,212,214] Although "common types" (usually the isolation of at least five to eight strains of a serotype during the period studied) occurred during each period and at each place, different types were "common" findings in different places and times. For example, Monto and colleagues,[212,214] during two 6-year study periods in Tecumseh obtained 475 HRV isolates covering 70 serotypes (of a possible 89 at that time),[169] but only HRV-1B, HRV-10, HRV-28, and HRV-58 were isolated in both periods. However, these viruses were not particularly common because only 16, 22, 15, and 18 isolates, respectively, of these four types were found during the 12 years. In the neighboring state of Wisconsin from 1963 to 1965,[68] the common types were HRV-43, HRV-51, and HRV-55, which were completely different from those in Michigan. Finally, the late John Fox sifted data from family populations surveyed by him and others in New York City, Seattle, and Tecumseh.[98,99] He found only 4 common serotypes (HRV-1B, HRV-12, HRV-15, and HRV-38) from among 802 isolates. Dominant HRV serotypes often appear to occur locally over relatively short periods but do not extend for decades or over the nation, at least in the United States.

More recent studies using molecular assays indicate that the number of circulating strains in a given geographic area is even greater than previously appreciated using only cell culture methods. Investigators in the Netherlands identified 27 different genotypes of HRV infection among a cohort of 18 healthy children 7 years of age and younger sampled at least every 2 weeks over a 6-month period.[287] Mackay and colleagues[193] identified 74 distinct HRV genotypes from all 3 HRV species circulating over a 1-year period in 234 children in Melbourne, Australia. Thus, the diversity of HRVs present in a community is greater than previously recognized.

Median Human Infectious Dose for Rhinovirus

As documented in HRV challenge experiments with laboratory-grown virus administered by nose drops or aerosol, less than one median tissue culture infective dose ($TCID_{50}$) can initiate infection.[64,76] Much more (2000 times) is required when placed on the tongue or dried just outside the anterior nares (10,000 times).[64] How accurately these conditions approach the natural state is not known.

PERSON-TO-PERSON TRANSMISSION

Epidemiologic Observations

Individual HRV serotypes often disseminate with surprising difficulty, as noted in studies of Eagle Heights Village,[68] a Madison, Wisconsin, elementary school, and a Chicago nursery school.[26] At least within family populations, the most common finding was that a specific HRV serotype did not spread from the index case. Hendley and associates,[142] in a study of 19 families in Charlottesville, found that HRVs from 10 of 22 index cases did not spread at all, and in only 7 families did dissemination to at least another person take place. In only 4 of the 19 families did further sequential spread occur. Fox and associates,[98,99] in a surveillance of more than 200 Seattle families, found intrafamily secondary attack rates in susceptible individuals (no homotypic antibody) to be 44 percent from 1965 to 1969 and 28 percent from 1975 to 1979. In both periods, children younger than 5 years had the highest secondary attack rate of 60 and 30 percent, respectively. Monto and Johnson and others[211,215] reported similar findings in 48 Panamanian families: with 5 HRV isolates used as antigens, the secondary attack rate varied from 10.5 to 56 percent.

In Madison, interfamily and intrafamily dissemination of the 3 "spreading" HRV types, HRV-43, HRV-51, and HRV-55, was examined in the 24 to 26 neighboring families living in fourplex apartments in Eagle Heights Village (Fig. 166-4). These 3 serotypes were the only ones of 14 to spread beyond the index family. HRV-51 attacked 23 percent of susceptible individuals, and many family members and close neighbors remained uninfected. HRV-43 infected 34 percent of susceptible individuals; in one building, only the families in a single-end fourplex became infected. Conversely, HRV-55 caused a mini-epidemic in two buildings; several families had all members infected. HRV dissemination seemed to focus on the fourplex, probably because in the winter months the children played in the hallways and stairs connecting the apartments. Nonetheless, even the spreading HRVs left many susceptible individuals untouched among next-door neighbors and within many families.

Determination of the reason for such erratic spreading patterns can be sought in well-controlled chain-of-infection experiments with human volunteers. HRV transmission experiments from several laboratories are described next.

Person-to-Person Transmission to Human Volunteers

Early Experiments with Rhinovirus Colds

Early experiments with different HRV serotypes showed that person-to-person transmission occurred infrequently. Couch and colleagues[59,63] attained no transmission after housing 15 donors (persons infected intranasally with laboratory-grown HRV-15) with 12 antibody-negative recipients for 26 days. At approximately the same time, the Madison laboratory performed transmission trials with HRV-55 and HRV-16 in a series of experiments ranging in duration from a 1- to 1.5-minute kiss to a 3-day weekend in a dormitory room. In 26 donors and 33 recipients, only two transmissions occurred, one from a 1.5-minute kiss and the other from a weekend in a dormitory.[64] Only when young married student couples were used was a substantial rate attained; among 24 couples, 9 donor spouses infected their mates, for a transmission rate of 38 percent.[65]

Characteristics of a "Good" Rhinovirus Transmitter

In the experiments with married couples, "successful" donors shed enough virus to contaminate their environment, exhibited signs and symptoms of a moderate to severe cold, and spent many hours at home with their spouses.[65] As an example of the effect of high virus shedding, intracouple transmission rates were 71 percent for donors with nasopharyngeal HRV titers of 5,000 to more than 80,000 $TCID_{50}$, 33 percent for those with 1,000 to 5,000 $TCID_{50}$, and only 18 percent for those with less than 1,000 $TCID_{50}$ ($p = .025$). Illustrative of both shedding and production of sufficient nasal secretions was contamination of the hands with HRV: donors whose hands were assayed for virus and who transmitted infections to their spouses all had HRV on their hands, whereas none of the nontransmitters did ($p = .03$). The amount of time spent together seemed important in transmission, although many infected spouses who spent hours of direct contact with their partners did not transmit the infection.

Some Early Conclusions

The preceding epidemiologic human volunteer studies suggest that attending a concert with persons who have even obvious signs of colds is unlikely to result in infection. Conversely, students who spend day after day in classrooms may have a higher chance of acquiring infection. In addition, a relatively short stay (a few hours) among friends or relatives with HRV-caused colds is not likely to cause infection, even with brief embracing.

Route-of-Transmission Experiments

Because HRVs often seem to spread with relative difficulty under many normal circumstances, the route of transmission becomes important because controlling respiratory virus transmission in habitats such as schoolrooms and families may be feasible by blocking transmission routes. Since the early 1970s, human volunteer experimental infection models have been used to explore HRV transmission routes. These studies were performed primarily at the University of Virginia, England's Common Cold Unit, and the University of Wisconsin.

Gwaltney and Hendley[123] at the University of Virginia focused on the possibility that HRV colds were disseminated by direct or indirect hand contact. Interest in this approach had been provoked by the inadvertent transmission of HRVs from infected to noninfected persons through the vehicle of an ethanol-sterilized nasal speculum. Subsequently, the plausibility of direct hand transmission of HRVs was supported by the observation that nose picking and eye rubbing were common among Department of Medicine Grand Rounds participants and Sunday school attendees,[143] following previous documentation of infection through conjunctival swabs.[37] These investigators then showed that HRV-39 retained infectivity for several hours on various surfaces and could be found on the hands of persons infected with HRV-39. In another study, infectious HRV was isolated from the fingertips of 22 percent of persons who touched objects that had been contaminated with nasal mucus of adults with natural colds one hour earlier.[299] These experiments suggest that transmission of HRV could occur through self-inoculation by environmentally contaminated hands and demonstrated HRV-39 self-inoculation from an environmental source in human volunteers.[143]

The University of Virginia team in Charlottesville subsequently conducted a series of three experiments that identified direct inoculation as a route of HRV transmission.[125] In two of the experiments, groups of recipients were exposed to aerosols generated by donors infected with an untypeable HRV strain, HH, and the exposures occurred in separate closed rooms for large-particle (12 recipients) or small-particle (10 recipients) aerosols produced by donors during periods of 45 minutes (large particles) or 3 days (small particles). One of the large-particle aerosol recipients was infected, whereas no one exposed to small-particle aerosols was. These essentially negative transmission rates by aerosol exposure were not surprising.[123] Previously, Couch[60] had been unsuccessful in transmitting infection through the airborne route over a period of 26 days, and the Madison laboratory attained only a single HRV transmission among 11 recipients after 3 days' exposure in a dormitory.[64] The third group of Charlottesville recipients was exposed to HRV by inoculating themselves with the donor's nasal mucus. The donors blew their noses into their hands. The recipients then stroked the donors' contaminated hands for 10 seconds and then inoculated themselves by deliberately placing their fingers, two or three times, on their nasal and conjunctival mucosa on 3 successive days. Eleven of the 15 hand-contact recipients (73%) were infected with the donors' HRV. The authors concluded that transmission by the hand-contact/self-inoculation route was much more efficient than the aerosol route was and "may be an important natural route of HRV transmission."[125]

One deficiency of this experiment was that donors and recipients shared the same air space over a measured, often brief, period during which fresh nasal mucus was transferred from the donor to the recipient. Nonetheless, Gwaltney did achieve a high rate of HRV transmission with nasal secretions, something that had not been accomplished readily in more "natural" experiments.[59,64] Also in support of hand transmission was the observation in the aforementioned married couple experiments that the ability to transmit HRV was correlated significantly with the presence of the virus on the donors' hands.[65] As a result of these various pieces of evidence and lack of compelling evidence to the contrary, hand-to-hand or fomite transmission became the accepted route for HRV contagion.[40,60] In later experiments, the Charlottesville group demonstrated approximately 50 percent transmission through fomites by using the same hand-contact/self-inoculation method described earlier, except either a coffee cup handle or a plastic tile was interposed between donors' and recipients' hands.[124]

At England's Common Cold Unit, Reed[241] investigated the likelihood of natural hand-contact transmission among residents (roommates) of several housing units, 38 of whom had been infected with HRV-2. Reed[244] found

that 16 of the donors had HRV on their fingers, but none of the virus was transmitted to the fingers of their 18 roommates, even though virus could be recovered from some (6 of 40) objects recently handled by HRV-2–infected donors. Reed also found that none of 29 virus transfers from virus dried on the fingers could pass through a fomite to a recipient; the conclusion was that "spread of colds is unlikely to occur via objects contaminated by the hands of the virus shedder …"

Laboratory workers at the University of Wisconsin continued their attempts to devise a natural transmission model to examine routes of transmission and, potentially, methods for interruption of transmission. Although the results of the transmission experiment with married couples were illuminating, the system itself had one great deficiency as an experimental model: the participants could not be observed during their interaction periods.[65] A model was needed in which donors and recipients could be monitored at all times. Ultimately, the scheme for such a system was suggested by two virologic-epidemiologic events in Antarctica, one from the summer seasons of 1975 to 1980 in which Dick and associates studied respiratory virus dissemination in an isolated Antarctic population and the other from a human volunteer experiment conducted in an Antarctic field party by England's Common Cold Unit.[291] Both experiences suggested that high natural transmission rates after just a few days of exposure could be achieved only in an environment with a high donor-to-recipient ratio and in a population density like that in classrooms and dormitories of a boarding school. Accordingly, a model was devised in which donors (with the qualities of a "good" transmitter as described earlier) and recipients interacted during waking hours by playing cards and board and video games and engaging in communal studying. During the night, donors and recipients bunked together in the same or an adjoining room. With such an arrangement, graduate student monitors recorded activities and all clinical signs 24 hours a day. These artifices were successful; with 8 donors and 12 to 16 recipients, a 50 percent recipient attack rate usually was attained over a 12-hour period and a 100 percent rate over the course of a week.[74,204] Informally, this model, a fully observed monotypic HRV mini-epidemic, was named "Antarctic Hut," from its origins.[141]

Route-of-Transmission "Blocking" Experiments

With the use of the Antarctic Hut model, a series of four HRV-16 route-of-transmission blocking experiments was conducted to determine whether the virus was spread by hand contact, aerosol, or both.[74] The first three experiments lasted 12 hours, with 8 donors and 12 recipients; the donor-recipient interaction was through playing variants of stud and draw poker (Fig. 166-5). This interaction mode facilitated both aerosol and fomite/hand-contact transmission. Half the recipients were blocked completely from any hand contact/self-inoculation by wearing arm restraints (see Fig. 166-5). Little transmission resulted from hand or fomite contact because the HRV-16 infection rate in the restrained recipients was only slightly lower than in the unrestrained recipients, 56 versus 67 percent, an insignificant reduction ($p = .494$).

The fourth experiment, involving aerosol blocking, was begun immediately after the third. The poker game

FIGURE 166-5 ■ A typical "Antarctic Hut" transmission experiment in progress using stud and draw poker as the interaction promoter. At each of four tables are two "donors" (infected with rhinovirus type 16) and three "recipients" (no antibody to rhinovirus type 16) (wearing surgical scrub suits). This particular experiment is one in which hand-contact/self-inoculation transmission is blocked in 6 of the 12 recipients by wearing Thatcher collars. The collars block hand-contact transmission by preventing touching of the face by the hands; therefore, virus can pass from donors to recipients only by aerosol.

continued in the original room with eight donors alone, and all the equipment from the third experiment, including the cards (which literally were gummy from the previous 12-hour game), poker chips, pencils, and so forth, was moved to an identical room across the hall. The continuing eight-donor poker game in the room used for the third experiment was refurnished with poker implements. Subsequently, 12 new recipients entered the second room, began playing poker with the now heavily used cards and other paraphernalia, and made exaggerated hand-to-nose self-inoculation movements. Aerosol transmission was blocked effectively by the two brick walls between the rooms. Once each hour, the cards, poker chips, and other portables were exchanged between the donor and recipient rooms to maintain a freshly contaminated supply of fomites in the recipient room. The result was extremely surprising; not 1 of the 12 "fomite recipients" caught HRV-16. Judging from the results of these Antarctic Hut experiments in which fomite/hand-contact and aerosol transmission were blocked alternately, aerosol transmission clearly seemed the predominant route, at least for HRV-16 among student poker players at the University of Wisconsin. A few months after the 1987 publication of these results, an editorial appeared in *The Lancet* titled "Splints Don't Stop Colds: Surprising!"[74,263] It concluded that "… it looks as though coughs and sneezes *do* spread these diseases more than sticky fingers."

Subsequently, a set of experiments was conducted to determine how HRV-16 had disappeared along the five-step fomite transmission chain from nose to hand to fomite to hand to nose.[163] The same results were noted.[244] The virus seemed to disappear precipitously at each step in the chain; 10^6 $TCID_{50}$ of HRV-16 in the donor's nose was reduced to 0 to 64 $TCID_{50}$ on the card-playing implements, and then the virus nearly disappeared on reaching the recipients' hands.

Additional studies examined other methods to interrupt transmission. The University of Virginia team performed a blocking experiment in the field in which mothers attempted to prevent hand contact/self-inoculation by dipping their fingers in iodine. The results of this 1979 to 1982 study were reported as part of a general review.[141] The illness rate during the 4 years was 40 percent lower in the mothers with iodinated fingers than in the placebo mothers, and the difference was significant ($p = .047$). However, the authors noted the difficulty of conducting and interpreting these investigations.[141] In another set of experimental human infection studies, the application of organic acids present in hand cleansers (e.g., salicylic acid, pyroglutamic acid) to the hands of volunteers decreased the likelihood of rhinovirus infection when volunteers subsequently touched their nasal or conjunctival mucosa 10 minutes after rhinovirus had been placed on their hands.[276]

The Madison group also examined transmission interruption methods to prevent spread from person to person. As part of a general investigation of the epidemiology of respiratory viruses in an isolated (≈200 persons) Antarctic population at McMurdo Station in 1979, use of an iodinated facial tissue developed by the S. C. Johnson Company of Racine, Wisconsin, was successful in interrupting transmission.[71,291] Three days after all personnel began copious use of these tissues, the incidence of respiratory illness dropped rapidly and significantly ($p < .01$); in fact, respiratory illness nearly disappeared from the base.[73] Although this effect was striking, the trial could be controlled only historically. However, the apparent success was sufficient to interest the Kimberly-Clark Corporation in applying virucidal facial tissue technology to interrupt HRV-16 transmission in the Antarctic Hut model. The Kimberly-Clark Corporation soon made available a nontoxic, highly virucidal facial tissue. The tissues completely stopped transmission of HRV-16, in comparison to transmission rates of 42 and 75 percent in control recipients using ordinary cotton handkerchiefs ($p < .001$) (Table 166-1).[72] The corporation test-marketed these tissues under the brand name "Avert," but their sales were lower than expected. Subsequently, two field trials of Avert in families were conducted in Charlottesville and Tecumseh, with reductions in viral transmission of 5 to 39 percent, respectively.[91,189] These results were disappointing but not unexpected. Changing established habits of personal nasal sanitation was not easy in the highly supervised, well-motivated adults in Antarctica; it may be impossible in unsupervised children.

Despite all the experimental studies to identify the principal route of virus transmission, no single route

TABLE 166-1 **Apparent Complete Interruption by Virucidal Tissues of Rhinovirus Type 16 Transmission***

Study Group	Cotton Handkerchiefs Experiment A	Virucidal Tissues Experiment B	Virucidal Tissues Experiment C	Cotton Handkerchiefs Experiment D
Recipients who "caught" HRV-16 colds/total (%)†	5/12 (42)	0/12	0/12	9/12 (75)

*In each of four experiments, 8 volunteers with HRV-16 colds played poker for 12 hours with 12 other volunteers (without HRV-16 antibody) and for nasal sanitation used either ordinary cotton handkerchiefs (experiments A and D) or virucidal tissues (experiments B and C). Three-ply Kleenex tissues were treated, per 100 g, with 9.1 g citric acid, 4.5 g malic acid, and 1.8 g sodium lauryl sulfate. Cotton or paper handkerchiefs were used to clear nasal passages, to smother coughs and sneezes, and to wipe surfaces. Virucidal tissues were used carefully and copiously.

†Diagnosed by at least one isolation of HRV-16 or a fourfold rise in antibody to HRV-16 in the convalescent serum sample, or both.

HRV-16, human rhinovirus type 16.

appears to be predominant. What is clear from these studies is that rhinovirus illnesses may be transmitted by both the hand-contact and aerosol routes.

PATHOGENESIS AND HOST FACTORS

General Course of Infection

Infection usually occurs through the respiratory route, although infection by the conjunctival route has been demonstrated.[37,143] When the virus is given intranasally by pipette, only one $TCID_{50}$ is needed to initiate infection.[64,76] The incubation period for a cold normally is 2 to 3 days, but a period of up to 7 days has been reported.[78,142] Ciliary dysfunction can predispose to respiratory tract infection.[29,39] HRVs replicate well in the upper respiratory tract (see later discussion), and substantial evidence indicates that they replicate in the lower respiratory tract as well.[109,129,224,225]

HRVs may be shed in large amounts (1000 to 1 million infectious particles per milliliter of nasal washing) during the first 2 to 3 days of a cold and may be produced for 2 to 3 weeks thereafter.[74,76,78,204] However, the effect on cells of the nasopharyngeal cavity seems benign despite much local reaction to the virus, which results in the usual signs and symptoms of a cold. Systematic studies of HRV-inoculated human volunteers at the University of Virginia demonstrated that damage to the respiratory epithelium was slight, although a few sloughed ciliated epithelial cells did contain HRV antigen.[277,295] HRV was recovered only at focal sites in the nose and nasopharynx at the time of maximal symptoms, and in situ hybridization studies demonstrated evidence of HRV infection in only a minority of epithelial cells.[15,23,297] Using primary monolayer cultures of ciliated and nonciliated epithelial cells, Winther and associates[296] demonstrated that HRV, coronavirus, influenza A virus, and adenovirus all grew well in these cell cultures; however, HRV and coronavirus produced no discernible cytopathic effect compared with the widespread destruction of the cell monolayer by influenza virus and adenovirus by 96 hours.

Innate Immune Response

Innate immunity is the initial host response to infection with rhinoviruses. Toll-like receptor 3 (TLR3) is activated during virus replication, is upregulated during HRV infection, and is associated with decreased viral replication.[145] Signaling occurs through both retinoic acid inducible gene-I (RIG-I) and melanoma differentiation associate gene-5, and inhibition of these molecules leads to increased viral replication.[264] One mechanism of inhibition of intracellular signaling developed by the virus is cleavage of the signaling molecules (e.g., RIG-I, interferon-β [IFN-β] promoter stimulator 1 [IPS-1]) by the viral protease.[24,84] Toll-like receptor activation leads to the production of type 1 IFNs, which is likely the mechanism by which viral replication is inhibited. Impaired induction of IFN-β leads to increased viral replication and is a defect that has been identified in the respiratory epithelium of asthmatic patients.[290] Numerous other components of innate immunity are also induced by rhinovirus infection, including β-defensins, nitric oxide, and a variety of proinflammatory cytokines and chemokines (e.g., interleukin [IL]-1, IL-6, IL-8, RANTES [regulated on activation, normal T cell expressed and secreted]).[241,253]

Because HRVs seem to cause only mild pathologic changes in cells of the respiratory tract, attention has turned to various immunologic or inflammatory substances as possible causes of symptomatic illness.[272] Researchers have long known that peripheral blood neutrophils increase in the first 2 to 3 days of illness in HRV-infected volunteers.[41,272] Phagocytes (neutrophils and monocytes) also have been demonstrated in large numbers in the nasal secretions of HRV-infected symptomatic human volunteers.[188] Although the microbe-killing ability of phagocytes is well known, these cells in themselves also can cause cold symptoms through the release of various toxic products, such as superoxide and hydrogen peroxide, during the respiratory burst.[35,269] In fact, increasing numbers of leukocytes in the peripheral blood correlate with increased symptoms and in infected human volunteers who are not ill the white blood cell count does not increase.[272] An association has been noted between the nasal levels of two proinflammatory mediators involved in granulocyte regulation, granulocyte colony-stimulating factor and IL-8, and blood and nasal neutrophilia have been identified.[110,221] Nasal IL-8 levels also correlate with the severity of clinical symptoms.[117,279]

Increased nasal levels of other inflammatory mediators (e.g., IL-1β, IL-6, RANTES, kinins) have been associated with more severe clinical symptoms.[218,221,238,239,306] Furthermore, topical nasal administration of IL-6 or bradykinin leads to development of some of the symptoms of the common cold.[105,240] At least some of these inflammatory responses appear to depend on an activation pathway regulated by nuclear factor κB (NF-κB).[305,306] Resolution of clinical symptoms may be caused by the elaboration of inhibitors of inflammation, such as IL-1 receptor antagonist.[303] These inflammatory mediators may serve as a target for the development of drugs to relieve the symptoms of HRV infection, although the use of a specific kinin inhibitor did not lead to clinical improvement.[120,147]

Immunity Associated with Serum Antibody

Serum antibody to the various HRV types develops with age (presumably from repeated infections); and by adulthood, antibody may be detected against approximately 50 percent of HRV types tested.[121] The presence of serum antibody correlates positively with immunity, and resistance to infection and the degree of disease expression are related to the amount of antibody present.[2,3,36] As examples, in the Eagle Heights Village families, 21 of 75 persons (28%) without antibody were infected with either HRV-43 or HRV-55, whereas only 5 of 35 (14%) with homologous antibody to either of these agents were infected.[68] No one was infected who had homologous

serum antibody levels above 1:16. Similar results were observed in the Charlottesville and Seattle families.[98,99,142] However, large doses can overwhelm antibody. At the clinical center of the National Institute of Allergy and Infectious Diseases, where human volunteers were used, 1000 $TCID_{50}$ was found to infect persons with serum antibody titers up to 1:256.[42] Judging from the paucity of reports of natural infections in persons with serum antibody titers greater than 1:16, virus inocula in naturally contracted cases must be low.

Immunity Associated with Antibody in Nasal Secretions

Researchers at the National Institutes of Health found that the presence of antibody in nasal secretion is associated with protection from homologous HRV infection and disease.[43] They found that intranasal administration of inactivated HRV vaccine produced both serum and nasal antibody, whereas two intramuscular injections of this vaccine produced little, if any, nasal antibody.[229] When the volunteers given the vaccine intranasally were challenged with approximately 100 $TCID_{50}$ of homologous HRV, they were protected significantly against both clinical illness and infection, whereas those administered the same vaccine intramuscularly remained susceptible.[229]

Conversely, when the same vaccine preparation was administered subcutaneously in three injections, nasal antibody responses were observed in 21 of 46 (45%) volunteers.[79] Challenge of these volunteers with 3 $TCID_{50}$ of virus produced significantly less virus shedding and reduced the duration and severity of illness than was observed in unimmunized controls who had no HRV-specific antibody. Possibly, this lower infectious dose more closely approximates a natural situation. This study also showed that protection against infection with the low virus challenge correlated with the magnitude of serum antibody and not with the presence of secretory antibody. The relative roles of serum and secretory antibody in HRV infections are still unsettled.

Antibody Appearance over the Course of Infection

A general pattern of the development of humoral (secretory and serum) antibody based on human studies has emerged.[36,81] Approximately 24 hours after infection, a sharp increase in nasal immunoglobulin (Ig) A secretion occurs. At the time symptoms appear (approximately 48 hours after infection), rhinorrhea begins, and the transudate is composed of significant amounts of IgG. After approximately 1 week and after the actual episode of illness, virus-specific antibody, predominantly IgA, appears in the nasal passages, tears, and the parotid saliva. Serum antibody (usually IgG but occasionally IgM) also begins to be formed at 1 week and rises to peak levels at 1 month. Both serum and secretory antibodies appear sooner and rise more rapidly in persons with detectable neutralizing antibody in their preinfection serum specimens. Antibody has been detected in nasal secretions and serum approximately 1 year after infection and, judging from the high proportion of the adult population with antibody to many HRV serotypes, probably lasts much longer.[33,121]

Cell-Mediated Immunity

Substantial evidence indicates that neutrophils increase both in the peripheral blood and in the nasopharynx during the first few days of an HRV cold.[41,294] Peripheral blood lymphocytes actually decrease in the first 2 to 3 days of an HRV cold, and migration of lymphocytes into the nasal secretions increases at this time.[41,188] Specific humoral antibody usually is not present in the serum or nasopharynx this early in the illness, a finding suggesting that these in situ nasopharyngeal lymphocytes, through cell-mediated immunity, play an important role in controlling HRV proliferation. HRV infection of primary epithelial cells cultured in vitro leads to increased expression of the T-cell attractant molecule CXCL10; and activated T cells cocultured with the epithelial cells produce IFN-γ and tumor necrosis factor (TNF) and activate the nitric oxide pathway, which can help inhibit viral replication.[166] Hsia and colleagues[150] examined the ability of peripheral blood lymphocytes to liberate various cytokines (IL-2 and IFN-γ) and participate in other cellular immune processes (cytotoxicity and antigen-stimulated blastogenesis) during the early days of HRV colds in experimentally infected human volunteers. These investigators found that all these cell-mediated immunity activities during infection were increased significantly when compared with preinfection levels. Of special interest, the cellular ability to liberate higher levels of IL-2 correlated inversely and significantly ($p < .02$) with virus shedding and nasal mucus production. Cross-reactive T-cell epitopes are shared by HRVs, and T cells isolated from peripheral blood and from tonsillar tissue proliferate and secrete a variety of cytokines (IFN-γ, IL-2, IL-4, IL-5) after exposure to HRV antigens.[108,135,293] Thus, activation of T cells may contribute not only to virus clearance but also to airway inflammation.[108]

Interference Among Rhinoviruses

Interference in infection with heterotypic HRV serotypes, which lasts between 5 and 16 weeks, has been reported in human volunteers.[92] Complete resistance to infection was observed after inoculation with as much as 2000 $TCID_{50}$ of HRV-16 (administered by nasopharyngeal spray) in a subject with an unsuspected "wild" HRV (not typed) infection present at the time of inoculation.[186] However, epidemiologic studies in a nursery school population,[26] a military population,[246] and a family population[209] showed sequential heterotypic HRV infections occurring frequently, sometimes at intervals as short as 2 days. In the family population, one subject was infected by three different HRVs within a 30-day period. The factor or factors responsible for the interference observed in the experimental human infection model have not been identified. Simultaneous infection with an HRV and other respiratory viruses, including influenza A and B

viruses, coronaviruses, parainfluenza type 1 virus, respiratory syncytial virus (RSV), adenoviruses, various enteroviruses, or other HRV serotypes, also has been commonly reported, particularly in children.[85,99,184]

Influence of a Cold Environment on the Course of Infection

Exposure to cold temperatures has been thought either to initiate or to exacerbate respiratory tract infections. In fact, chilling animals was shown to increase the severity and frequency of viral infection.[289] However, investigation of the effects of chilling on humans infected with "common cold viruses" and with HRV-15 did not demonstrate significant effects.[80] In the HRV-15 experiments, the conditions were realistic. The subjects (men) were cooled sufficiently in air to cause shivering for approximately an hour or were immersed in water long enough to cause a decline in rectal temperature.

Effect of Age and Sex

A much higher prevalence of HRV infection is found in infants and young children than in older persons. In Seattle,[98] the HRV infection rate in children from birth to 5 years of age was nearly twice that of older children and adults (0.77 vs. 0.41 infections per person per year, respectively); in Tecumseh,[214] the isolation rate in the 1- to 4-year-old group was far higher than that in any other age bracket. The high attack rates in these young children were not unexpected because fewer than 10 percent of them had antibody to any of the 56 HRV types,[123] and children ordinarily are subjected continuously to the family-like environment so conducive to transmission of HRVs. In especially crowded populations, attack rates may be high. In an Alaskan Eskimo village, 70 percent of 395 children were infected during a spring outbreak of HRV-16 infection.[300]

The frequency of infection with HRV generally declines throughout life. In a prospective study of children attending daycare where PCR methods were utilized to analyze samples collected weekly in symptomatic children, HRVs were the most common respiratory virus identified (Fig. 166-6), and the incidence/child-year of HRV infection was 1.3/year for children enrolled in daycare at birth to 12 months of age versus 0.8 for children older than 12 to 24 months.[90] Beginning at the age of school attendance, the number of HRV infections declines gradually from one to two per year to 0.25 per year in the age group older than 60 years.[121,216] Results from most laboratories have found that persons 20 to 30 years of age account for an exception to the general decline in incidence with age[98,142,213,216]; HRV infections as well as infections with other respiratory pathogens increase during this period of life. Because the increase is especially marked in mothers,[98,142] it probably is the result of the transfer of respiratory illness in small children to parents.

In Tecumseh, the number of respiratory illnesses per year was consistently higher for female patients than for male patients (3 to >60 years of age).[216] If one assumes that HRVs account for a similar proportion of disease in each gender, this finding would indicate that girls and women generally have more HRV infections. As noted earlier, women with young children clearly seem to have more HRV infections than do others in their age group. In Seattle,[98] mothers had 1.5 times more HRV infections than fathers did, and in Charlottesville, women of childbearing age had approximately 1.2 times more HRV illness than male study subjects did.[121]

The number of moderate to severe rhinovirus illnesses was higher in boys than girls during the first 3 years of life in a longitudinal birth cohort study examining factors associated with developing wheezing illness.[284] However, the number of HRV-associated wheezing illnesses was similar between the two sexes.

Effect of Psychosocial Factors

Numerous psychosocial factors have been shown to influence susceptibility to HRV infection, primarily in the experimental human infection model. Increased psychological stress, as measured by numerous stress indices, and poorer sleep efficiency were associated with an increased susceptibility to infection and an increased likelihood of developing illness.[50,52,53] In contrast, having a more diverse societal network (increased number of social ties) and having a positive emotional style (i.e., sense of well-being, vigor, and calmness) were associated with resistance to infection and illness.[51,83] Antibody-negative (serum antibody levels < 1:2) subjects were equally susceptible to infection regardless of the degree

Epidemiology of viral respiratory tract infections in a prospective cohort of infants and toddlers attending daycare. *J Clin Virol* 2010;**49**:16-20.)

of stress or number of social ties, although these factors did influence the likelihood of clinical illness.[51,52] Increased stress in working adults also was associated with an increased risk for having a natural common cold.[268]

CLINICAL MANIFESTATIONS

HRV infections in any age group usually cause only mild upper respiratory tract illness or common colds.[60] Investigators estimate that HRVs cause 30 to 50 percent of common colds, at least in adults.[191] A variety of respiratory symptoms and signs can be present, and the relative frequency varies of such symptoms varies between children and adults (Table 166-2). The development of serious illness is also possible: HRV-associated, radiograph-positive, atypical pneumonia has been described in military trainees[106] and in immunocompromised adults,[112,154] graft dysfunction has occurred in lung transplant recipients,[168] and exacerbation of underlying lung disease has been seen in adults with asthma and chronic obstructive pulmonary disease.[19,114,219,257] Severe respiratory disease, pneumonia, and death also have occurred in outbreaks of rhinovirus infection in geriatric patients residing in nursing homes.[146,190]

Children, particularly the very young, are subject to serious, sometimes fatal HRV-caused illness. These include bronchiolitis and pneumonia. Viremia has been noted to occur in a minority of children with HRV infection and respiratory disease.[301] Deaths of infants with rhinoviremia has also been observed, including one of which that occurred during a cold and six "cot" deaths that were diagnosed as bronchiolitis/pneumonia and from which HRVs were isolated.[245,286] At least in theory, generalized illness after viremia seems possible with HRV infections; the HRVs are a division of the larger picornavirus group, which contains many viruses capable of generalized and fatal infection and whose genomes have considerable homology with the HRVs (see Structure of the Virion, earlier).[222] HRVs have also been isolated from patients with a variety of other respiratory clinical illnesses, including pharyngitis, epiglottitis, and laryngotracheobronchitis (croup) (Table 166-3). However, detection of HRV may also occur in persons who are

totally asymptomatic; up to 25 percent of infections detected by PCR assay in otherwise healthy children and adults are asymptomatic or subclinical,[155,259] and asymptomatic shedding for up to 3 months has been documented even in hematopoietic stem cell transplant recipients.[205]

Spectrum of Respiratory Disease

Rhinovirus Infections in Hospitalized Children

Many investigators have identified HRV infections in children hospitalized with severe respiratory disease, and these studies illustrate the high number of hospitalizations associated with HRV in children overall. In 1971 in Bristol, England, prior to the widespread use of molecular diagnostic tools, 377 infants hospitalized for respiratory disease yielded 199 (53%) viral diagnoses.[160] RSV was predominant and accounted for 79 percent of the diagnoses, but HRVs were second at 12 percent (23 patients). Half of the HRV diagnoses were in infants with bronchiolitis or pneumonia. HRV illnesses were comparable in severity to those caused by RSV.

At St. Anna Children's Hospital in Vienna from 1984 to 1986, Kellner and colleagues[172] compared the clinical features of HRV and RSV infection in 519 children aged 10 days to 3 years (median age, 6.6 months). Viral pathogens were detected in 227 (44%) of the children; and of these, 119 (23%) were RSV and 60 (12%) were HRV. The physical findings (Table 166-4) and the clinical diagnosis (see Table 166-3) of the children with HRV or RSV infection were the same, except HRV infections were more likely than were RSV infections to be associated with upper respiratory tract infection.

Glezen and colleagues[113] performed a prospective study to evaluate the occurrence of respiratory virus infection in subjects with respiratory or cardiac disorders in Houston, Texas, between 1991 and 1995. HRV infections were identified in 51 subjects from a total of 1198 evaluated illnesses; 6 were associated with a second respiratory virus infection.[88] In children younger than 5 years of age, exacerbation of asthma, bronchiolitis, and suspected sepsis were the most common clinical findings, whereas in older children and young adults, almost all subjects had an exacerbation of asthma. In older adults, a complication of an underlying disease (asthma, chronic obstructive lung disease, congestive heart failure) or pneumonia was diagnosed. In this prospective study, HRV infections were an important cause of lower respiratory tract illness in all age groups.[88] When molecular methods were used to identify viral respiratory tract infections from specimens collected during this study, HRVs were present in almost 25 percent of analyzed samples and in approximately half of children younger than 1 year of age.[20]

Bronchiolitis is one of the more common reasons for young children to be hospitalized with respiratory illness. HRVs have been identified in several studies as the second most common virus infection identified in association with bronchiolitis after RSV.[38,161,196,197] In some studies, the bronchiolitis associated with HRV infection was less severe than that caused by RSV,[196-198,265] whereas in others the severity was similar.[38] In a large multicenter study reported by Mansbach and colleagues,[196] children younger than 2 years of age and coinfected with RSV and HRV had significantly longer lengths of stay after adjustment for clinical and demographic parameters whereas HRV coinfections with other respiratory viruses were not

associated with prolonged lengths of stay. Decreased severity of illness in hospitalized children who are coinfected with both HRV and RSV or human metapneumovirus has also been documented.[30,198]

Several studies have examined the prevalence of HRV infection in pediatric patients presenting with community-acquired pneumonia. Juven and colleagues[167] examined 254 children hospitalized with community-acquired pneumonia and found HRV infection in 25 percent. A concomitant bacterial co-pathogen was identified in half of the patients. Tsolia and associates[271] reported HRV infection in 45 percent of 75 school-aged children hospitalized with community-acquired pneumonia, with a co-pathogen found in 58 percent of the HRV-infected patients. García-García and colleagues[104] detected HRV infection in approximately 20 percent of children hospitalized with pneumonia; HRV was the most common viral pathogen identified in children older than 18 months of age and the sole virus identified in 55 percent of the HRV-infected patients.

Iwane and colleagues[155] examined the contribution of HRVs in children younger than 5 years of age who were hospitalized with severe acute respiratory illness. Overall, HRV infection was identified in 17.4 percent of the children, and a second viral respiratory pathogen was identified in 18 percent of HRV-infected patients (most commonly RSV). These investigators also included a control group of age-similar children presenting for well-child visits and without active respiratory symptoms, and they found that 12.5 percent of the control subjects were asymptomatically infected with HRV. Infection with HRV-A viruses was significantly more common in the hospitalized children 24 months of age and older compared with controls (8.1% vs. 2.2%), and HRV-C infection was significantly more frequent in hospitalized children 6 months of age and older (8.2% vs. 3.9%). HRV-B infection was uncommon in both groups (<1% each).

In summary, there is substantial evidence that HRVs can cause serious lower respiratory tract illness, especially in young children. In some populations, HRVs may be second to RSV in frequency and be associated with comparably severe signs and symptoms. However, the prevalence of asymptomatic virus shedding and the frequent identification of another viral respiratory tract infection make it difficult to determine the clinical significance of HRV infection in the individual patient.

Asthma

HRV infection is a risk factor for both the development of asthma and for exacerbations of wheezing in children with asthma. Having either an RSV or an HRV infection that results in a wheezing illness during the first year of life is an independent risk factor for wheezing later in childhood.[178,180,187] Children who have a HRV-associated wheezing illness in the first 3 years of life are more likely to be diagnosed with asthma at 6 years of age than are those who had an RSV-associated illness.[156] Sensitization to aeroallergens (atopy) in the first year of life also was an independent risk factor for the subsequent development of asthma, particularly after HRV infection.[156,157,180] It is still not clear at this time whether the infection with HRV (or RSV) that is associated with wheezing in the first several years of life plays an etiologic role in the subsequent development of asthma or whether it is a marker for children already at risk for developing asthma.[175]

Viral respiratory tract infection is a common precipitant of wheezing in children with asthma.[34] HRVs are the most frequent respiratory virus identified in children with acute wheezing exacerbation of asthma; however, not all HRV infections in an asthmatic child will result in wheezing. Two investigative groups serotyped the HRVs isolated from children with wheezy illness and found no types to be particularly "asthmagenic"; and a total of 30 different serotypes were associated with asthma exacerbations.[170,206-208] At the present time it is not clear whether HRV strain differences are important factors in precipitating asthma attacks.

The mechanism of bronchospasm in virus-infected patients has generated much speculation and research. HRVs can replicate in the lower respiratory tract and have been found in the lower airways.[109,129,152,224,225] Whether the virus-associated bronchospasm is caused by viral replication in the lower airways or by induction of inflammatory mediators resulting from their growth in the upper respiratory tract has been a subject of debate, although accumulating evidence favors the former possibility.[107] HRV infection clearly induces the production of numerous proinflammatory cytokines, and an increased number of inflammatory cells has been demonstrated in the lower respiratory tract in association with HRV infection.[94,102,107] The presence of activated cytotoxic T cells in the lower airways has been suggested to contribute to asthma-associated mortality.[220] Host factors also play a role, in that innate immune responses to rhinovirus are impaired. For example, bronchial epithelial cells from asthmatic individuals produce less IFN-β and have less apoptosis and greater viral replication after infection with HRV than do cells from nonasthmatic subjects.[290] Aeroallergen–sensitized asthmatic children have higher expression of the high affinity IgE receptor FcεRI than nonallergic, nonasthmatic children, and this was associated with a decreased production of IFN-α and IFN-γ1 by plasma-derived dendritic cells after HRV stimulation.[87] IFN production was further decreased after cross linking of the FcεRI receptor. Animal models also suggest the possibility that reflex neurogenic pathways may be activated in association with viral respiratory tract infection and may lead to bronchoconstriction. The pathogenesis of respiratory virus–induced bronchospasm is an area of active research, with the hope that preventive or therapeutic intervention strategies can be developed.

Otitis Media

Although acute otitis media is chiefly a bacterial disease, with approximately two thirds of middle ear fluid specimens yielding *Streptococcus pneumoniae*, *Haemophilus influenzae*, or both, and *Moraxella catarrhalis* and other bacteria playing lesser roles, otitic involvement often is preceded or accompanied by a putative viral upper respiratory tract illness.[11,13,177,251] Most bacterial pathogens found in

middle ear fluid are colonizers of the nasopharynx, and bacterial infection of the middle ear is considered to be a direct extension from that area.[177] A history of a preceding viral upper respiratory tract illness is common, and clear and comprehensive evidence of viral extension from the nasopharynx to the middle ear has been established. Many different respiratory viruses have been identified in middle ear effusions from children with otitis media, and HRVs are one of the most commonly identified when molecular methods of detection are used. Pitkaranta and colleagues[234] identified respiratory viruses from the middle ear effusions in 30 percent of 100 children who had otitis media with effusion. HRVs constituted approximately two thirds of the respiratory viruses identified. Bacterial pathogens were identified in 35 percent of the samples, and both bacteria and viruses were found in 11 percent. A criterion for selection was the absence of an upper respiratory tract illness within the preceding week, thus whether the presence of HRV RNA represented evidence of ongoing or past infection is unclear. Blomqvist and colleagues[27] found HRV RNA in middle ear effusions from 41 percent of children with otitis media in the first 2 years of life, and Chantzi and colleagues[45] found a similar prevalence of HRV RNA in otitis media effusions.

The presence of both bacterial and viral pathogens in middle ear fluid does not, in general, interfere with the effectiveness of antibacterial therapy, although in those specific patients whose acute otitis media is refractory to treatment it may.[14] When measured against a comparison group of 66 "normal" acute otitis media cases (controls), 22 patients with refractory cases harbored significantly more viral pathogens than did controls (68% vs. 41%, respectively; $p < .05$). In addition, when only the middle ear fluid of these groups was examined for the presence of viruses, 32 percent of patients with refractory cases had virus versus 15 percent in controls. HRVs were the dominant viruses in both groups. Bacterial pathogens were grown from the middle ear fluid of 4 of the 22 in the poor-responder group, and all harbored concomitant respiratory viruses, two of which were HRVs; only one of the four bacteria was resistant to the antibacterial agent used in therapy. These investigators also examined patients in the 66-patient control group whose illnesses were refractory to treatment and found significantly more viruses ($p < .05$) in the middle ear fluid of this group than in those with a good response to therapy. These authors concluded that the presence of viruses in the middle ear fluid of children with acute otitis media can delay response to antibacterial therapy.

Chonmaitree and associates[47] in Galveston, Texas, also investigated the role of viruses in middle ear fluid as agents that may interfere with antibacterial therapy. In their initial report, viruses were cultured from the middle ear fluid of 11 of 58 children (19%); RSV and HRV were the most frequent viruses isolated, at 3 each. Of the patients in whom therapy failed, significantly more ($p < .05$) harbored viruses as well, and of those whose bacteria were susceptible to the treatment antibiotic, significantly more had combined viral-bacterial infections. In two subsequent reports by these authors, the highest rate of poor bacteriologic outcome occurred when HRV was isolated from middle ear fluid. Seven of nine instances of HRV infection resulted in bacteriologic treatment failure.[267]

These studies suggest that viruses, including HRVs, may play a role in acute otitis media, especially in prolonging the response to antimicrobial treatment. McBride and associates[200] at the University of Pittsburgh and the University of Virginia used HRV-infected human volunteers and found that the eustachian tube became occluded in 50 percent of the volunteers and that abnormal middle ear pressure was present for as long as 10 days. These studies were extended by Buchman and colleagues,[32] who inoculated 60 volunteers with HRV-39. Middle ear pressures of less than –100 mm H_2O were noted in 22 subjects (37%). In 2 of the 3 subjects who had pressures less than –100 mm H_2O, upper respiratory tract illness with middle ear effusion developed. In this study, the otologic manifestations of experimental HRV infection were extended to include otitis media.

Arola and colleagues[12] examined the role of viruses in 61 children (mean age, 3.2 years) with subacute or chronic asymptomatic otitis media with effusion. Five HRVs and one adenovirus were found in the middle ear fluid. In addition, bacterial pathogens were isolated from the patient with adenovirus infection and from two of the patients with HRV infection. None of these patients with otitis media and effusion were ill with an upper respiratory tract infection at the time the specimen was obtained, and the effusion had endured 30 to 60 days before myringotomy was performed.

Sinusitis

HRVs can cause a clinical syndrome of rhinosinusitis similar to that caused by bacterial infection. Gwaltney and colleagues[126] performed computed tomography of the sinuses on adults with acute common colds of less than 4 days' duration in which HRV infection was documented by culture in 27 percent. Radiographic abnormalities included mucosal thickening and air-fluid levels. Associated clinical signs and symptoms resolved without antibiotic therapy, a finding suggesting that the radiographic signs were caused by an acute viral infection. Few attempts have been made to recover viruses directly from the sinuses. Two reports from Virginia noted that 140 aspirates obtained by direct puncture of the maxillary sinuses yielded 86 positive specimens, only 12 of which contained viruses. Seven of these viruses were HRVs, and the remainder were influenza A or parainfluenza viruses.[127,130] Five of the viruses were isolated in conjunction with bacterial pathogens. In a more recent study, Pitkaranta and associates[233,235] used real-time PCR analysis and in situ hybridization to identify HRVs in 50 percent of adults with acute community-acquired sinusitis. Because the signs and symptoms of viral rhinosinusitis and bacterial sinusitis can be difficult to distinguish, the American Academy of Pediatrics developed clinical practice guidelines for the diagnosis and treatment of bacterial sinusitis, and these were updated in 2012 by the Infectious Diseases Society of America.[48,49]

Immunocompromised Patients

Community-acquired respiratory viral infections are important causes of morbidity and mortality in immunocompromised patients.[89] HRV infections in these populations are common, with a cumulative 100-day incidence as high as 22.3 percent in one hematopoietic stem cell transplant population and with infections occurring year round and prolonged virus shedding noted.[205] Clinical manifestations can range from mild upper respiratory tract symptoms to fatal pneumonia.[112,119,205] Many patients with fatal infections have been coinfected with other pathogens, making it difficult to determine the relative contribution of HRV infection to the outcome.[12,154] Overall, higher viral loads in clinical samples correlated with more symptomatic and more severe disease.[111,205]

DIAGNOSIS OF INFECTION

HRV infections cannot be diagnosed solely on the basis of clinical grounds because they cause such a wide spectrum of respiratory illness, particularly in infants and children. However, because of the characteristic spring-summer-fall seasonal pattern of the HRVs, tentatively assigning an HRV origin in patients with mild-to-moderate respiratory illness during these months is not unreasonable.

Obtaining a culture of the etiologic agent and interpreting the meaning of a positive specimen can be difficult with HRVs. These viruses often propagate unpredictably, even in relatively sensitive diploid cell cultures such as WI-38 and FT cells or in Ohio strain HeLa cells, and none of the HRV-C strains can be propagated in vitro,[16,55,58,61,121] Isolation of HRV from children can also be hampered by the common practice of relying on a throat swab. Inocula from many throat swabs contain one tissue culture infectious virus particle or less (see Table 166-5). Hendley and colleagues[142] found nasal specimens to be superior for HRV studies, and diagnostic rhinovirologists from many nations successfully use nasal aspirates.[149,171,203] Specimens should be placed in cell culture as soon as possible and without previous freezing and thawing (however, refrigeration [4° C] overnight results in little loss). If freezing is necessary and dry ice is used, great care must be taken to avoid contamination of the specimen with sublimed carbon dioxide because the resultant carbonic acid rapidly kills the virus. Cell cultures should be incubated at 33° C and slowly rolled. Evidence of virus growth usually is seen between 2 days and 2 weeks. Once a cytopathic effect is evident, standard techniques for identification are used.[62]

As described early in this chapter, HRVs have many base sequences in common among the RNA genomes of the various serotypes, especially in the noncoding region at the 5′ end. Several laboratories have taken advantage of this observation by designing RT-PCR assays for the detection of HRVs. Some assays do not distinguish HRVs from enteroviruses, whereas others are HRV specific.[103,128,153] The superiority of RT-PCR techniques compared with cell culture methods first became evident in a clinical study of children with acute respiratory illnesses. Johnston and colleagues[165] detected HRV by PCR in 146 of 292 samples (50%) that yielded HRV in only 47 (16%) by standard culture. PCR was thus three times more sensitive than was culture for detecting HRV infection. Many subsequent studies confirmed the superiority of RT-PCR assays over culture methods for the detection of HRVs.[4,18,19,151] The development of sensitive real-time RT-PCR assays raises the possibility that clinical virology laboratories would become able to identify HRV infection rapidly.[255] Multiplex assays that identify HRVs as well as other respiratory viruses are also commercially available.[22,232] The increased sensitivity of molecular assays can make interpretation of a positive result problematic, because many asymptomatic infections are identified. Viral quantitation may have a role in identifying clinically significant HRV infections.[111]

TABLE 166-5 **Quantity of Virus Found in 87 Throat Swab Squeezings from Children Aged 3 to 11 Years: Madison, Wisconsin, from 1971 to 1972***

	Per 0.1 mL
≤1 $TCID_{50}$	22
>1 to ≤50 $TCID_{50}$	46
≥50 to <50 $TCID_{50}$	14
>50 to <500 $TCID_{50}$	5

*Fourteen rhinovirus types are represented.
$TCID_{50}$, median tissue culture infective dose.

PREVENTION AND TREATMENT

Prevention and treatment are addressed thoroughly in Chapter 7 and elsewhere, and only measures specific to the HRVs are added here. Although some protection after the use of inactivated vaccines has been demonstrated,[79,230] the existence of more than 100 serotypes limits the prospect of vaccine development. However, based on the observation that cross-reacting antigenic groupings exist among the HRVs, developing a vaccine that targets these epitopes may be possible.[57]

The most effective HRV cold-preventive agent described to date that has been demonstrated to be effective for natural HRV colds is IFN-α, a protein produced as part of the host's natural antiviral defense and now produced for experimentation by genetic recombinant methods.[82,136] Investigators administered this agent by nasal spray to other family members after symptoms appeared in the index case; 80 percent of the secondary HRV colds were prevented. However, IFN given in this fashion does not seem to be effective against other respiratory viruses. For example, in a follow-up study in Seattle, IFN-α did not reduce the incidence of colds when administered in a protocol identical to that used in the previous family studies, chiefly because HRV infections were not the majority of agents causing colds.[77,82,101,136]

HRVs often have a decided seasonality, so rapid diagnosis of the index case by PCR analysis would be helpful to determine when IFN-α could be used effectively to stop intrafamily spread. A combination of rapid diagnosis and family prophylaxis with IFN-α could be helpful in families such as those with asthmatic children, in whom HRV infection may be serious (see Clinical Manifestations). The disadvantage of IFN prophylaxis is that prolonged intranasal administration (>7 days) or repeated treatment produces an inflammatory response consisting of nasal stuffiness, ulceration, and blood-tinged discharge.[252]

Numerous antiviral agents with in vitro activity against HRVs have been developed. The earlier section in this chapter on structure of the virion describes the development of some of these agents, which was made possible by taking advantage of current detailed knowledge of HRV structure and specific cell receptors. Several of these preparations, including capsid-binding agents, soluble receptor (soluble ICAM-1), and antibody to the receptor (ICAM-1), have been tested in clinical trials, but development of most of these agents has not been pursued for a variety of reasons,[21,278] as reviewed by Arruda and Hayden.[17] Another capsid-binding agent, pleconaril, has in vitro antiviral activity against many enteroviruses and HRVs, and phase III clinical trials on naturally acquired colds demonstrated some reduction in the severity and duration of several respiratory symptoms.[137] However, pleconaril induces the cyp3A4 enzyme that can lead to menstrual irregularities in women taking oral contraceptives.[93] This concern, along with the drug's modest efficacy, prevented pleconaril from being approved by the U.S. Food and Drug Administration; an intranasal form is still under development.[226] Another anti-RV drug, rupintrivir (formerly AG7088), is a potent, irreversible inhibitor of viral 3C protease that has reached clinical trial.[138,199] Further studies of both these agents, especially in children, will be needed to determine their potential benefits.

Colds usually are treated symptomatically with mild nonsteroidal anti-inflammatory drugs, sympathomimetics (e.g., phenylpropanolamine), and antihistamines; these agents are discussed in Chapter 7.[262] Anticholinergic agents (e.g., topical ipratropium bromide) and first-generation antihistamines reduce severity of rhinorrhea, whereas second-generation ("nonsedating") antihistamines have no effect. The efficacy of the first-generation antihistamines may result from the ability of these agents to block muscarinic as well as histaminic receptors and to cross the blood-brain barrier.[217] Sympathomimetics decrease nasal obstruction, although topical administration may lead to rebound nasal obstruction. Nonsteroidal anti-inflammatory agents decrease the severity of some of the systemic symptoms associated with colds (e.g., malaise, headache).[273] A combination of antiviral and antimediator preparations may provide effective therapy.[122] Various other treatments, including vitamin C,[44,140] *Echinacea*,[202,274] intranasal humidified air,[96,281] and zinc lozenges,[159,194,236] have been evaluated, and some studies have reported a clinical benefit, although other studies have failed to confirm such findings.[273] Almost all clinical evaluations of symptomatic and alternative therapies have been performed in adults; very few data exist on the utility of such therapy in children.[194,260] In 2007, the U.S. Food and Drug Administration released a warning against using over-the-counter therapies including antihistamines, decongestants, and antitussives for the treatment of the common cold in children younger than 2 years of age because of potentially dangerous side effects linked to several deaths, in the absence of data demonstrating benefit in this age group.[95]

The use of oral or inhaled corticosteroids appears to enhance the shedding of viable virus.[118,242] One potential consequence of corticosteroid use, seen in a study of pediatric patients with a common cold syndrome, is a significant increase in the risk for developing acute otitis media in HRV-infected subjects.[250] However, hospitalized children with a first episode of wheezing associated with HRV infection were less likely to have recurrent wheezing over the following year if treated with prednisolone, and corticosteroid therapy can decrease the duration of symptoms associated with acute asthma exacerbations.[162,185] Thus, corticosteroids do not have a role in the treatment of uncomplicated HRV infections. Similarly, no role exists for the use of antibiotic therapy in uncomplicated HRV infection.

Acknowledgment

The authors would like to acknowledge the contributions of Elliot C. Dick, Stanley L. Inhorn, and W. Paul Glezen, who contributed to this chapter in previous editions of the text.
